(Received 10 June 1999; published 22 February 2000)

We present a lattice NRQCD study of the B meson decay constant in the quenched approximation with emphasis given to the scaling behavior. The NRQCD action and the heavy-light axial vector current we use include all terms of order 1/M and the perturbative O(αsα) and O(αs/M) corrections. Using simulations at three values of couplings β = 5.7, 5.9, and 6.1 on lattices of sizes 12 3 × 32, 16 3 × 48, and 24 3 × 64, we find a significant α dependence disappears in fB if the O(αs,α) correction is included in the axial vector current. We observe that β = 5.9−6.1 is the window where systematic errors are expected to be minimum within one-loop improved theory. Our final results are \( f_{B} = 170(5)(15) \) MeV, \( f_{B} = 191(4)(17)(t_{0}^{2}) \) MeV, and \( f_{B} = 1.12(2)(1)(t_{0}^{2}) \), where the first error is statistical, the second is systematic, and the third is due to the uncertainty of the strange quark mass, while quenching errors are not included.

I. INTRODUCTION

Lattice QCD provides a promising approach for a first-principles calculation of the hadronic matrix elements of B meson relevant for a precision determination of the Cabibbo-Kobayashi-Maskawa matrix elements. Among the most important matrix elements is the B meson leptonic decay constant \( f_{B} \), which is needed to determine \( V_{td} \). From the theoretical point of view it is the simplest B meson matrix element calculable in lattice QCD, with which one can study systematic errors associated with a lattice treatment of heavy quarks.

The need for a careful examination of systematic errors stems from the fact that their magnitude for naive quark action is of \( O(αM) \) with \( M \) the heavy quark mass. Hence errors of this origin can exceed 100% for a typical lattice spacing of \( a^{-1} \sim 2 \) GeV used in current simulations. To overcome this problem, recent lattice studies of \( f_{B} \) [1] employ a nonrelativistic effective theory of QCD (NRQCD) [2] or a nonrelativistic interpretation of the relativistic lattice quark action for heavy quarks [3].

NRQCD is an effective theory formulated as an expansion in \( D/M \) where \( D \) is the spatial covariant derivative which is of \( O(Λ_{QCD}) \) for the heavy-light system. For NRQCD one has to choose the coefficients of the expansion by imposing a matching condition with the full theory. This can be made by using perturbation theory. In practice one has to truncate both nonrelativistic expansion and perturbative expansion at some order so that the systematic error in NRQCD calculations is organized as a double expansion in \( Λ_{QCD}/M \) and the strong coupling constant \( αs \).

An additional source of systematic errors is the discretization error proportional to some power of \( aΛ_{QCD} \). Since NRQCD is valid only when \( aM>O(1) \), the continuum limit \( a→0 \) cannot be taken. Therefore, removing discretization errors is more important in this formalism than in the usual relativistic formulations for which continuum extrapolations can in principle be made. For this reason, in many lattice NRQCD calculations, the correction terms to remove \( aΛ_{QCD} \) and even \( (aΛ_{QCD})^{2} \) errors were introduced to allow a scaling behavior at a larger lattice spacing.

Until recently the matching coefficients for the action [4–6] and the current operators [7] were available only at one-loop level without operator mixing. This means that \( O(αsΛ_{QCD}/M) \) and \( O(αsAA_{QCD}) \) errors were left unremoved. Recently, Shigemitsu and Morningstar carried out a one-loop calculation necessary for \( O(αsΛ_{QCD}/M) \) and \( O(αsAA_{QCD}) \) improvement of the heavy-light axial vector current [8,9]. The first simulation including this improvement was performed by Ali Khan et al. [10,11], in which they pointed out that the \( O(αsΛ_{QCD}/M) \) and \( O(αsAA_{QCD}) \) terms significantly affect the values of \( f_{B} \).

The study of Ali Khan et al. [10,11] was made at a single lattice spacing corresponding to the inverse gauge coupling \( β=6/g^{2}=6.0 \), and hence left open the important question of the lattice spacing dependence of \( f_{B} \) obtained with lattice NRQCD (in Refs. [12] Hein has calculated \( f_{B} \) at \( β=5.7 \) and discuss the scaling behavior by combining the result at \( β=6.0 \) of Ref. [11]). This question is particularly important, since a correct choice of lattice scaling is crucial in NRQCD, where two contradictory requirements compete: i.e., the \( a→0 \) limit cannot be taken while scaling violation requires \( a \) to be sufficiently small.

In this article we report on our study concerning this question. Our simulations are carried out with the plaquette ac-
tion for gluons at $\beta=5.7$, 5.9, and 6.1 corresponding to the range of lattice spacing $a=0.18-0.09$ fm. For light quark we employ the $O(a)$-improved Wilson (clover) action [13] with the tadpole improved one-loop value for the clover coefficient [14,15]. We investigate in detail the effect of one-loop improvement of the heavy-light axial vector current as a function of the lattice spacing. Our final results are presented with the action correct to $O(1/M)$, after verifying with the action complete to $O(1/M^2)$ that higher order corrections are not important.

This paper is organized as follows. In Sec. II we summarize the NRQCD action we use. In Sec. III improvement of the axial vector current is discussed, and our one-loop mixing coefficients are presented. Details of the simulations and our methods for extraction of the decay constant are given in Sec. IV together with numerical results. We discuss the effect of improvement in the static limit in Sec. V. Our results for $f_B$ are presented in Sec. VI where a comparison is made with those obtained with the relativistic formalism. In Sec. VII the hyperfine splitting of the $B$ meson and the $B_s$ mass difference are given. Our conclusions are summarized in Sec. VIII.

II. LATTEC NRQCD ACTION

Form of action

Let us denote by $Q(t,x)$ the two-component heavy quark field. This field evolves in the time direction according to the action,

$$S = \sum_{t,x} Q^\dagger(t,x) [Q(t,x) - K_t Q(t-1,x)],$$

where the operator $K_t$ specifies the evolution; our choice is

$$K_t = \left( 1 - \frac{aH_0}{2n} \right)_t \left( 1 - \frac{a\delta H}{2} \right)_t U_{4t-1}^{-1} \left( 1 - \frac{a\delta H}{2} \right)_{t-1} \left( 1 - \frac{aH_0}{2n} \right)_t. \tag{2}$$

Here subscripts represent the time slice at which Hamiltonian operators such as $(1-aH_0/2n)$ act, and an integer $n$ is introduced to suppress instability appearing in the evolution equation due to unphysical momentum modes [2]. We note that the ordering of terms in Eq. (2) is different from the one employed in [11]: the factor $(1-a\delta H/2)$ is placed inside of $(1-aH_0/2n)$ in our choice.

The leading order Hamiltonian $H_0$ is given by

$$H_0 = -\frac{\Delta^{(2)}}{2M_0}. \tag{3}$$

For the correction term $\delta H$, we consider two choices corresponding to the nonrelativistic expansion to order $1/M$ ($\delta H_I$) or to order $1/M^2$ ($\delta H_II$), given by

$$\delta H_{II} = -c_1 \frac{g}{2M_0} \sigma \cdot B + c_2 \frac{ig}{8M_0^2} (\Delta^{(2)} - E \cdot E \cdot \Delta^{(2)})$$

$$- c_3 \frac{g}{8M_0^2} \sigma \cdot (\Delta^{(2)} \times E - E \times \Delta^{(2)})$$

$$- c_4 \frac{(\Delta^{(2)})^2}{8M_0^4} + c_5 \frac{a^2 \Delta^{(4)}}{24M_0^4} - c_6 \frac{a(\Delta^{(2)})^2}{16nM_0^4}. \tag{5}$$

We refer to the two choices as NRQCD-I and NRQCD-II. We work with both Hamiltonians in parallel and compare their results in order to examine effects of truncation in the $1/M$ expansion. Various covariant differential operators in the Hamiltonian are defined in terms of the forward and backward derivatives $\Delta^{(n)}_\mu$ and $\Delta^{(n)}_\nu$ in the $\mu$-th direction as $\Delta^{(n)}_\mu = (\Delta^{(n)}_\mu + \Delta^{(n)}_\nu)/2$, $\Delta^{(2)}_\mu = \Delta^{(1)}_\mu \Delta^{(1)}_\nu$, $\Delta^{(2)} = \sum_{\nu=1}^3 \Delta^{(2)}_\nu$, and $\Delta^{(4)} = \sum_{\mu=1}^3 \Delta^{(2)}_\mu$. The field strength operators $B$ and $E$ are constructed with the clover-leaf definition as in Ref. [2]. The bare heavy quark mass is denoted as $M_0$, and $c_i$’s specify the strength of each term.

The relativistic four-component field $\psi_B$ is related to the effective field $Q$ through the Foldy-Wouthuysen-Tani (FWT) transformation:

$$\psi_B(t,x) = R Q(t,x). \tag{6}$$

Here the transformation operator $R$ is given by

$$R_1 = 1 - d_1 \frac{\gamma \cdot \Delta^{(2)}}{2M_0}, \tag{7}$$

$$R_{II} = 1 - d_1 \frac{\gamma \cdot \Delta^{(2)}}{2M_0} + d_2 \frac{\Delta^{(2)}}{8M_0^2} + d_3 \frac{g}{8M_0^2} \Sigma \cdot B$$

$$- d_4 \frac{ig}{4M_0^2} \gamma_4 \gamma \cdot E, \tag{8}$$

with $\Sigma = \text{diag}(\sigma^i,\sigma^i)$, and $R_1 (R_{II})$ is to be used in conjunction with $\delta H_I (\delta H_{II})$ to achieve the desired accuracy in the $1/M$ expansion.

The coefficients $c_i$ and $d_i$ should be determined by matching the action to the continuum relativistic QCD action by either resorting to perturbation theory or estimating it nonperturbatively so as to reproduce the same theory in each order of the $1/M$ expansion. So far even perturbative results are not available for these coefficients. We adopt the tree-level value $c_1 = 1$ and $d_1 = 1$ in our work, applying, however, the mean-field improvement to all link variables in the action and the FWT transformation with the replacement $U_{\mu} \rightarrow U_{\mu}/u_0$, where we take $u_0 = \langle \text{Tr} U_{\text{plaq}} \rangle^{1/4}$ [16].

III. IMPROVEMENT OF THE CURRENT

To calculate the decay constant $f_B$, the heavy-light axial vector current in lattice NRQCD has to be matched to that in continuum QCD. The overall renormalization factor $Z_A$ was first calculated by Davies and Thacker [7] by perturbation
theory to one-loop order. The calculation has been extended to include $O(\alpha_s a_L \Lambda_{QCD})$ and $O(\alpha_s \Lambda_{QCD}/M)$ by Shigemitsu and Morningstar [8,9]. Since we adopt a slightly different action, we have repeated a similar one-loop calculation.

Consider the axial vector current $A_{\text{cont}}$ in the continuum. We demand that on-shell $S$ matrix elements of the lattice axial current reproduce that of the continuum current up to $O(p)$ with $p$ the spatial momentum of the heavy or the light quark. At one-loop level the relation takes the form

$$ A_{\text{cont}} = \left[1 + \alpha_s \rho^{(0)}_A \right] J^{(0)}_{\text{lat}} + \alpha_s \rho^{(1)}_A J^{(1)}_{\text{lat}} + \alpha_s \rho^{(2)}_A J^{(2)}_{\text{lat}}, \quad (9) $$

where the heavy-light lattice operators of dimension 3 and 4 are defined by

$$ J^{(0)}_{\text{lat}} = \bar{\psi}_l \Gamma \gamma_5 \psi_h, \quad (10) $$

$$ J^{(1)}_{\text{lat}} = -\frac{1}{2M_0} \bar{\psi}_l \Gamma \gamma_\Delta \gamma_5 \psi_h, \quad (11) $$

$$ J^{(2)}_{\text{lat}} = \frac{1}{2M_0} \bar{\psi}_l \Gamma \gamma_\Delta \gamma^2 \psi_h, \quad (12) $$

with $\Gamma = \gamma_5 \gamma_4$ for the temporal axial vector current, and $\psi_l$ and $\psi_h$ denoting the light and heavy quark fields, respectively. We calculate the coefficients $\rho^{(i)}_A$ for NRQCD-I for the heavy quark and the $O(a)$-improved clover action [13] for the light quark. The use of clover action for the light quark is necessary to achieve the accuracy of $O(\alpha_s a a_L)$ in matching the current. For renormalization of the continuum current we adopt the $\overline{\text{MS}}$ scheme using dimensional regularization with fully anticommuting $\gamma_5$. We apply the tadpole improvement procedure [16] with the average plaquette to all link variables in the covariant derivative of the operators in Eqs. (11) and (12), and with the critical hopping parameter to the wave function renormalization of the light quark fields consistently in both nonperturbative and perturbative calculations.

Numerical results for the coefficients $\rho^{(i)}_A$ are listed in Table I, and plotted in Fig. 1 as a function of $1/aM_0$. For $\rho^{(0)}_A$ we plot $\rho^{(0)}_A - (1/\pi) \ln(aM_0)$, removing the logarithmic term appearing in the leading order of the renormalization factor $Z_A = 1 + \alpha_s \rho^{(0)}_A$. The other coefficients $\rho^{(1)}_A$ and $\rho^{(2)}_A$ are divided by $2aM_0$. The filled symbols represent the values obtained with the static action [17]. We have confirmed that the infinite mass limit of $\rho^{(0)}_A - (1/\pi) \ln(aM_0)$ agrees with the static results of Borrelli and Pittori [18] and of Golden and Hill [19].

We observe that $\rho^{(1)}_A/2aM_0$ vanishes in the limit $aM_0 \to \infty$, which tells us that the contribution of $\alpha_s \rho^{(1)}_A J^{(1)}_{\text{lat}}$ is of $O(\alpha_s \Lambda_{QCD}/M)$. This is expected since $J^{(1)}_{\text{lat}}$ involves a derivative of the heavy quark field. On the other hand, $\alpha_s \rho^{(2)}_A J^{(2)}_{\text{lat}}$ does not contain such a derivative, and $\rho^{(2)}_A/2aM_0$ remains finite in the static limit as seen in Fig. 1. Namely its contribution contains terms of $O(\alpha_s a \Lambda_{QCD})$. This term is an

**FIG. 1.** $1/aM_0$ dependence of the one-loop coefficients for the axial vector current. Circles represent $\rho^{(0)}_A - 1/\pi \ln(aM_0)$. Diamonds and triangles are $\rho^{(1)}_A/2aM_0$ and $\rho^{(2)}_A/2aM_0$, respectively. The static limit is shown with the filled symbols.
analogue of the current improvement term of $O(\alpha_s a)$ for the light quark discussed in Ref. [15]. We add a remark that we have repeated a one-loop calculation for the action employed in Ref. [9], and numerically confirmed their results to a three digit accuracy.

IV. DETAILS OF THE SIMULATION

A. Run parameters

We list our simulation parameters in Table II. Our simulations are carried out for three values of the coupling $\beta = 5.7, 5.9, \text{ and } 6.1$ with the standard plaquette action for gluons. These $\beta$ corresponds to $a = 0.18, 0.13, \text{ and } 0.09$ fm, respectively, if the scale is determined from the string tension. We choose our spatial lattice size to be larger than 2 fm.

For the heavy quark we take five values of the bare mass $m_0$ for each $\beta$ to cover a range of the physical heavy quark mass $M$ between 2 and 16 GeV. This wide range enables us to examine explicitly the $1/M$ dependence of $f_B$. The parameter $n$ is chosen so as to satisfy the stability condition $n > 3 \lambda_0 M_0$.

For the light quark we use the $O(\alpha)$-improved Wilson action [13] with the clover coefficient $c_{sw} = (1/a_0)^3 [1 + 0.199 \alpha_s (1/a)]$, which includes the $O(\alpha_s)$ correction calculated in Refs. [14,15]. Four values of the light quark hopping parameter $\kappa$ are employed for extrapolation to the chiral limit (see Table II for numerical values).

The value of the strange quark mass $m_s$ differs depending on whether $m_K$ or $m_\Delta$ is used as input; the value of $m_s$ determined with $m_\Delta$ is higher, and the discrepancy does not diminish for smaller lattice spacings. We choose to calculate $f_{B_{\bar{c}c}}$ for both $m_s$, and take the difference as a systematic error. The hopping parameters $\kappa_s$ ($\kappa_{s1}$ from $m_K$ and $\kappa_{s2}$ from $m_\Delta$) are also given in Table II.

The physical scale of lattice spacing is fixed using the string tension $\sigma = 427$ MeV. Recent data of the string tension are summarized in Ref. [20]. We adopt their parametrization to obtain the values of $1/a$ at our $\beta$.

B. Fitting procedure and data analysis

The method to extract the heavy-light decay constant is standard. We define a local and a smeared operator for the pseudoscalar channel by

$$O^P(t,x) = \bar{q}_i(t,x) \gamma_5 \psi_i(t,x),$$

$$O^S(t,x) = \sum_y \bar{q}_i(t,x) \gamma_5 \psi_i(t,y) \phi^{SRC}(|x-y|),$$

in the Coulomb gauge. For the smearing function we use $\phi^{SRC}(|x|) = \exp(-ax^2)$, with the parameters $a$ and $b$ chosen so as to reproduce the functional form of the heavy-light meson wave function measured in our simulations. We measure the two-point functions given by

$$C_{\bar{c}c}^{LS}(t_f,t_i) = \sum_{x_f} \langle O^L_{p}(t_f,x_f) \bar{O}^S_{p}(t_i,0) \rangle,$$

$$C_{\bar{c}c}^{SS}(t_f,t_i) = \sum_{x_f} \langle O^S_{p}(t_f,x_f) \bar{O}^S_{p}(t_i,0) \rangle,$$

$$C_{\bar{c}c}^{LS}(t_f,t_i) = \sum_{x_f} \langle J^{(1)}_{\text{int}}(t_f,x_f) \bar{O}^S_{p}(t_i,0) \rangle,$$

with the Dirichlet boundary condition in the temporal direction. In this measurement the source is placed at the time slice $t_i = 6$ (at $\beta = 5.7$), 7 (5.9), and 16 (6.1). For the heavy-light meson with zero spatial momentum, $C_{\bar{c}c}^{LS}(t_f,t_i)$ and $C_{\bar{c}c}^{LS}(t_f,t_i)$ are identical by construction.

We fit the correlators to the exponential form

$$C_{\bar{c}c}^{LS}(t_f,t_i) \rightarrow Z^{LS}_{PP} \exp[-a E_{\text{bin}}(t_f-t_i)],$$

$$C_{\bar{c}c}^{SS}(t_f,t_i) \rightarrow Z^{SS}_{PP} \exp[-a E_{\text{bin}}(t_f-t_i)],$$

$$C_{\bar{c}c}^{PS}(t_f,t_i) \rightarrow Z^{PS}_{PP} \exp[-a E_{\text{bin}}(t_f-t_i)],$$

over a range of $t$ where we find a plateau in the effective mass plot. Representative plots are shown for $C_{\bar{c}c}^{PS}(t_f,t_i)$, $C_{\bar{c}c}^{SS}(t_f,t_i)$, $C_{\bar{c}c}^{PS}(t_f,t_i)$, and $C_{\bar{c}c}^{PS}(t_f,t_i)$ in Figs. 2 (3) for the heaviest (lightest) quark mass at $\beta = 6.1$. The signal is remarkably clean even for $C_{\bar{c}c}^{PS}(t_f,t_i)$ which includes a spatial differential operator. To constrain the fit as tight as possible we take the binding energy $E_{\text{bin}}$ to be common among the correlators. This is particularly necessary for a stable extraction of $Z^{PS}_{PP}$ since the signal for $C_{\bar{c}c}^{PS}(t_f,t_i)$ is much noisier than for the others. We estimate statistical errors of the fitted
parameters using the jack-knife method with unit bin size. Statistical correlation of data between different time slices or between different mass parameters is neglected in the fitting.

C. Heavy-light meson mass

We calculate the pseudoscalar meson mass $aM_p$ from a sum of the renormalized heavy quark mass and the binding energy through the formula

$$aM_P = Z_m aM_0 - E + aE_{\text{bin}},$$

where $E$ is the energy shift and $Z_m$ the kinetic mass renormalization of the heavy quark.

The one-loop calculation of $E$ and $Z_m$ was carried out by Davies and Thacker [4] and by Morningstar [5]. We repeat the calculation for NRQCD-I. We write the perturbative expansion of $E$, $Z_m$ and the wave function renormalization $Z_{2h}$ as

\[
\text{FIG. 2. Effective mass of various correlators at } \beta=6.1 \text{ and } (aM_0, n) = (2.1, 2). \text{ The fitted value of } aE_{\text{bin}} \text{ is shown by a solid line, and the error is indicated by dashed lines. The light quark hopping parameter } \kappa=0.13586 \text{ is our heaviest one.}
\]

\[
\text{FIG. 3. Same as Fig. 2, but with our lightest light quark mass } \kappa=0.13716.
\]
and list A, B, and C in Table I.

**D. Heavy-light decay constant**

The pseudoscalar meson decay constant is given by

\[ a^{3/2}(f_P \sqrt{M_P}) = \frac{1}{\rho_{\text{lat}}(0)} \left[ 1 + \alpha_{\text{p}}(0) a^{3/2}(f_P \sqrt{M_P})^{(0)} \right] + \sum_{i=1}^{2} \alpha_{\text{p}}(i) a^{3/2}(f_P \sqrt{M_P})^{(i)}, \]

including one loop corrections, where \( J_{\text{lat}}^{(i)} \) are defined by

\[ a^{3/2}(f_P \sqrt{M_P})^{(i)} = \sqrt{2 \rho_{\text{lat}}(0)} \sqrt{1 - \frac{3 \kappa}{4 \kappa_{\text{crit}}}}, \]

with \( \sqrt{1 - 3 \kappa/4 \kappa_{\text{crit}}} \) the tadpole-improved wave function normalization factor for the light quark. We note that \( a^{3/2}(f_P \sqrt{M_P})^{(i)} = a^{3/2}(f_P \sqrt{M_P})^{(1)} \) holds in the rest frame of the heavy-light meson.

In Figs. 4 and 5 we show \( aE_{\text{bin}}^{\text{bin}} \) and \( a^{3/2}(f_P \sqrt{M_P})^{(i)} \) as a function of \( 1/\kappa \) together with a linear (solid lines) and a quadratic (dotted lines) fit. We employ the linear fit for the chiral extrapolation since the difference between the linear and the quadratic fits are negligibly small compared with errors of the data. The linear fit is also used for an interpolation to the strange quark. The values of \( aE_{\text{bin}}^{\text{bin}} \) and

\[ E = \alpha_{\text{A}}, \]

\[ Z_n = 1 + \alpha_{\text{B}}, \]

\[ Z_{2\ell} = 1 + \alpha_{\text{C}}, \]

and list A, B, and C in Table I.

**FIG. 4.** Chiral limit of the heavy-light binding energy \( aE_{\text{bin}}^{\text{bin}} \) at \( \beta = 6.1 \) and \( (aM_{\phi}, n) = (2.1, 2) \). Open diamonds represent our data. Filled diamonds are the results in the chiral limit (\( \kappa_{\text{crit}} \)) or in the strange quark mass (\( \kappa_{\ell1} \) or \( \kappa_{\ell3} \)) with linear fitting (solid line), and open squares are the results with quadratic fitting (dotted line).

**FIG. 5.** Chiral limit of the decay constant \( a^{3/2}(f_P \sqrt{M_P})^{(0)} \) (upper) and \( -2 a^{3/2}(f_P \sqrt{M_P})^{(0)} \) (lower) at \( \beta = 6.1 \) and \( (aM_{\phi}, n) = (2.1, 2) \). The meaning of the symbols is the same as that in Fig. 4.

**FIG. 6.** \( 1/M_P \) dependence of \( (f_P \sqrt{M_P})^{(0)} \). We used tree level value for \( M_P \) in the plot. Data at three \( \beta \) values are shown: \( \beta = 5.7 \) (diamonds), 5.9 (squares), and 6.1 (circles). The static limit (filled symbols) is obtained with a quadratic extrapolation.

</table>
we can see the effect of $O(\alpha_s \Lambda_{\text{QCD}})$ improvement more clearly.

According to the discussion in Sec. III, the contribution of \( J_{\text{lat}}^{(1)} \) vanishes in the static limit. From Eq. (9), the matching relation in the static limit for the axial vector current is given by

\[
A_{\text{4cont}} = [1 + \alpha_s \rho_{\text{static}}^{(0)}] J_{\text{static}}^{(0)} + \alpha_s \rho_{\text{static}}^{(\text{disc})} a J_{\text{static}}^{(\text{disc})},
\]

where $\rho_{\text{static}}^{(0)}$ and $J_{\text{static}}^{(0)}$ are the naive static limit (except anomalous dimension) of $\rho^{(0)}_A$ and $J_{\text{static}}^{(0)}$. $\rho_{\text{static}}$ and $J_{\text{static}}^{(\text{disc})}$ are defined as

\[
\rho_{\text{static}}^{(\text{disc})} = \lim_{a M_0 \to \infty} \rho_{\text{static}}^{(2)} / 2 a M_0,
\]

\[
a J_{\text{static}}^{(\text{disc})} = \lim_{a M_0 \to \infty} 2 a M_0 J_{\text{static}}^{(2)}.
\]

The numerical value of the matching coefficients in the static limit is given in Table I.

The decay constant is calculated from

\[
f_{\text{static}}^{B(s)} = \frac{f_{\text{static}}^{B(s)}}{\sqrt{M_{\text{static}}}}
\]

with

\[
(f_{\text{static}}^{B(s)})_{\text{static}} = \left[ 1 + \alpha_s \rho_{\text{static}}^{(0)} \right] (f_{\text{static}}^{B(s)})_{\text{static}} + \alpha_s \rho_{\text{static}}^{(\text{disc})} 2 a M_0 (f_{\text{static}}^{B(s)})_{\text{static}}.
\]

A nominal value of $M_0=4.5$ GeV is used for the heavy quark mass to evaluate the logarithm of $\rho_{\text{static}}^{(0)}$. For the strong coupling constant $\alpha_s$, we employ $\alpha_s(q^*)$ [16] evolved from $\mu=3.40/a$ to $q^*$. There is an uncertainty in the choice of the scale $q^*$ within one-loop calculations. We take the average of the results obtained with $q^*=\pi/a$ and with $1/a$, and consider the difference from the two choices of $q^*$ as an upper and lower bounds for the error due to two-loop corrections in the renormalization factor.

Figure 8 shows the $a$ dependence of the decay constant in the static limit, $f_B^{\text{static}}$ and $f_{B_s}^{\text{static}}$. Open symbols represent the results which are not corrected for the mixing effect of the operator $a J_{\text{static}}^{(\text{disc})}$ (which corresponds to the static limit of $2 a M_0 J_{\text{static}}^{(\text{disc})}$), and filled symbols include this effect. Statistical errors are shown with solid bars, and uncertainties due to the choice of $q^*$ by dotted bars. From the figure we see that an apparent $a$ dependence for the unimproved results is removed by the inclusion of the higher dimensional operator $J_{\text{static}}^{(\text{disc})}$ at the one-loop level.

A worry with this observation is a sizable systematic error due to two-loop uncertainties. On this point we note that the optimal value of $q^*$ for the multiplicative renormalization coefficient is known to be $q^*=2.18/a$ for the combination of the static heavy quark and the unimproved Wilson light quark [21]. Since there seems to be no obvious reason that this value changes significantly for the $O(\alpha)$-improved light quark action, taking the difference of the results for $q^*$
where the error is dominated by the uncertainty in $\alpha_i$. At $\beta=6.1$ the effect reduces $f_B^{\text{static}}$ by about 10% from the value without the improvement term.

### VI. $B$ Meson Decay Constant

#### A. Dependence on heavy-light meson mass

In Fig. 9 we present $\Phi_\beta = [\alpha_i(M_B)/\alpha_i(M_P)]^{2/11} f_B^{\text{static}} / f_B^{\text{static}}$ as a function of $1/M_B$ for three values of $\beta$. Open symbols denote results from the leading operator alone, and filled symbols show how they change due to the inclusion of the higher-dimensional operators $J^{(1)}_{\text{latt}}$ and $J^{(2)}_{\text{latt}}$. The factor $[\alpha_i(M_B)/\alpha_i(M_P)]^{2/11}$ is introduced to cancel the logarithmic divergence $(1/\pi)\ln(a M_0)$ in the one-loop coefficient $\rho_A^{(0)}$. For $\alpha_i(M_P)$ we use $\alpha_i(\mu)$ [16] evolved from $\mu=3.40/a$ to $M_P$. The chiral limit is taken for the light quark. Solid and dotted error bars show the statistical error and the uncertainty due to two-loop corrections in the renormalization factors. The latter is estimated in the same way as for the static limit discussed in Sec. V.

As first observed in Refs. [8,10,11], the contributions from the operators $J^{(1)}_{\text{latt}}$ and $J^{(2)}_{\text{latt}}$ sizably affects the decay constant. The dominant effect arises from $J^{(2)}_{\text{latt}}$. A larger difference between the two sets of results toward the static limit is explained by the fact that the one-loop coefficient $\rho_A^{(2)}/2a M_0$ increases toward this limit (see Fig. 1). In contrast, the contribution of $J^{(1)}_{\text{latt}}$ is negligible since the perturbative coefficient $\rho_A^{(1)}/2a M_0$ stays very small ($|\rho_A^{(1)}/2a M_0| < 0.2$) for our heavy quark mass $a M_0 > 1.2$.

As was the case for the decay constant in the static limit, uncertainties due to two-loop corrections are sizable, particularly at $\beta = 5.7$. This uncertainty does decrease, however, for weaker couplings at $\beta = 5.9$ and 6.1. It also becomes smaller as one moves down from the static limit toward the physical $B$ mass.

#### B. Dependence on lattice spacing

By interpolating data shown in Fig. 9 to the physical $B$ meson mass, we obtain $f_B$ for each $\beta$. The decay constant $f_{B_s}$ for $B_s$ meson is calculated in a similar manner. The bare $b$ quark mass that gives the physical $B$ meson is listed in Table VI, and $f_B$ and $f_{B_s}$ at each $\beta$ are given in Table VII for the two choices of the scale $q^* = \pi/a$ and $1/a$.

The lattice spacing dependence of $f_B$ and $f_{B_s}$ is shown in Fig. 10. Looking at the central values, we observe that a large $\alpha$ dependence exhibited in the data without the operator mixing (open symbols) is removed in the full result (filled symbols). This feature is clearer for $f_{B_s}$; a variation is seen for $f_B$ between $\beta = 5.9$ and 6.1, albeit with larger statistical errors. Keeping in mind the uncertainty due to the choice of $\alpha_i$, this result indicates that the lattice spacing dependence of the $B$ meson decay constant is sizable reduced after including the $O(\alpha, a)$ and $O(\alpha_i/M)$ mixing terms.
C. Estimate of systematic errors

We now discuss possible sources of systematic errors and estimate their magnitudes.

As already discussed the uncertainty from the scale for the strong coupling constant, which is an $O(a_s^2)$ effect, is sizable. The magnitude of this error, estimated as half the difference of values for $q^* = \pi/a$ and $1/a$ is given in Table VIII for each $b$.

We employ a light quark action which is $O(a)$-improved at one-loop level. Since the two-loop uncertainty in this improvement of $O(\alpha_s^2 a \Lambda_{\text{QCD}})$ is negligibly small, we expect the leading discretization error from the light quark sector to be $O((a \Lambda_{\text{QCD}})^2)$, which is also the magnitude of scaling violation in the gluon sector. With a nominal value $\Lambda_{\text{QCD}} = 300$ MeV, we estimate its size to be 2–8% depending on $b$ as listed in the table.

Our results are obtained for NRQCD-I which represents the leading term in an expansion in $1/M$. We examine corrections due to this truncation by comparing the results of NRQCD-I with NRQCD-II which is correct to $O(1/M^2)$. Figure 11 shows that the $1/M^2$ correction does not exceed the statistical error, which is about 4% in the $B$ meson mass region, as previously observed in Ref. [22]. Higher order uncertainties are expected to be even smaller.

</tbody>
</table>
Another source of the systematic error is the perturbative matching of the action and the operators of NRQCD. In the one-loop calculation of the self-energy and the current renormalization, we have consistently included all terms of order $\ln M$. Hence $O[\alpha_s/(aM)]$ corrections are properly taken into account in our calculation, and the leading error is of $O[\alpha_s/(aM)^2]$. An order estimate for $O[\alpha_s/(aM)^2]$ is given in Table VIII. The magnitude increases for larger $\beta$ since $aM$ becomes smaller.

Adding these four leading systematic errors in quadrature, we find the total systematic error to be about 8% at $\beta = 6.1$ and 5.9, while it is significantly larger ($\sim 15\%$) at $\beta = 5.7$. We expect that the systematic errors also increase beyond $\beta = 6.1$ as a fate of a nonrenormalizable effective theory. This means that $\beta = 5.9-6.1$ is a window where the systematic errors become minimum within the present framework of improvement. For our final result, we take the results at $\beta = 5.9$, for which none of the sources of the systematic uncertainty listed in Table VIII is particularly large. We note that the results at $\beta = 6.1$ are consistent with those at $\beta = 5.9$ within the estimated error.

There are two more sources giving systematic errors in $f_B$. One is due to the uncertainty of $1/k$. We estimate this error by taking the difference of the results with $m_K$ and those with $m_\rho$. The other is the $O(\alpha_s a m_\phi)$ error in the renormalization coefficient, arising from the fact that we used the coefficient with massless clover action for the light quark whereas the actual case is massive. We estimate this error to be $\sim 2-0.8\%$.

In addition to the above systematic uncertainties, we must include an uncertainty in the lattice scale $1/a$. Throughout this work we have used the scale set with the string tension $\sqrt{\sigma}$. Taking a variation of the ratio $m_\rho/\sqrt{\sigma}$ over $\beta = 5.9, 6.1$, and 6.3, we assign a 3.5% error in the lattice scale as we did in Ref. [23]. The scale obtained from the $\rho$ meson lies within this error range.

**D. Results**

Our final result for the $B$ meson decay constant in the quenched approximation is given by

$$ f_B = 170(5)(15) \text{ MeV}, $$

$$ f_B = 191(4)(17) \text{ MeV}. $$

Here the central value is the result at $\beta = 5.9$, and the errors are statistical and systematic in the given order. The systematic error includes 8% as estimated in the previous subsection and the error in the lattice scale of 3.5%, added in quadrature. For $f_B$, there is an additional uncertainty from the strange quark mass. We take the value from the $K$ meson mass ($\kappa_{s1}$) for our central value. Employing the $\phi$ mass ($\kappa_{s2}$) gives a larger $f_B$, which is given in the third parenthesis for $f_B$.

Our result is larger than that of Ali Khan et al. [11] at $\beta = 6.0$ [$f_B = 147(11)(16) \text{ MeV}$ and $f_{B_s} = 175(8)(18) \text{ MeV}$]. We quote the results from relativistic calculations of the Fermilab [24] group and JLQCD [23]:

$$ f_B = 164(14)(8) \text{ MeV (Fermilab)}, $$

$$ f_B = 173(4)(13) \text{ MeV (JLQCD)}, $$

$$ f_{B_s} = 185(13)(9) \text{ MeV (Fermilab)}, $$

$$ f_{B_s} = 199(3)(14) \text{ MeV (JLQCD)}. $$

Our results with NRQCD are in good agreement with these values.

**E. $f_B/f_{B_s}$**

Many systematic uncertainties that appear in the calculation of the pseudoscalar decay constant $f_{P(s)}$ cancel, if we
consider the ratio $f_{P_s}/f_{P}$. In particular, the two-loop uncertainty in the matching of the axial current cancels out explicitly.

Figure 12 presents the $1/\Lambda^2_{P}$ dependence of $f_{P_s}/f_{P}$. We observe only a mild $1/\Lambda^2_{P}$ dependence. The difference between NRQCD-I and NRQCD-II is much smaller than the statistical error. Namely, the contribution of the $1/\Lambda^4$ terms is negligible. Finally, plotting the ratio as a function of lattice spacing (see Fig. 13), we find the results at three $\beta$ values to be consistent with each other within errors.

Our result is

$$f_{B_s}/f_B = 1.12(2)(1)(^{+3}_{-0}),$$

at $\beta = 5.9$. The errors given are those from statistical, systematic and uncertainty in $\kappa_s$. Many systematic errors cancel in the ratio $f_{B_s}/f_B$. The leading remaining error arises from our use of the renormalization coefficient calculated for $m_s = 0$. This neglect of the mass dependence gives an error of $O(\alpha_s a m_s)$ for $f_B$, which reduces to $O(\alpha_s a \Lambda_{QCD})$ when divided by $f_B$. Our order estimate of this error is 3–5%.

VII. MASS SPLITTINGS

A by-product of our simulation is the mass difference between the $B$ and $B_s$ mesons, which can be compared with experiment. Since the heavy quark mass cancels in this difference, there are no direct perturbative corrections to this quantity, though they enter implicitly through bare $b$-quark mass.

We plot the $1/\Lambda^2_{P}$ dependence of the $B_s - B$ mass difference in Fig. 14, where we observe the dependence to be small. The lattice spacing dependence is shown in Fig. 15. A variation of about 20%, beyond the statistical error of 8%, is seen between $\beta = 6.1$ and 5.9, which may represent scaling violation. From the result at $\beta = 5.9$ we obtain

$$M_{B_s} - M_B = 78(5)(4)(^{+10}_{-8}) \text{ MeV},$$

where the meaning of errors is the same as above. The possible systematic error is $O((\alpha_s a \Lambda_{QCD})^2)$, which is 2–3%, and
the uncertainty of \( 1/a \sim 3.5\% \); we thus estimate the error to be 5\%.

Another interesting quantity is the hyperfine splitting \( M_{B_s} - M_B \). Previous lattice studies (in the quenched approximation) have shown that the hyperfine splittings of heavy-light and heavy-heavy mesons are much smaller than experiment [25]. A possible reason for this discrepancy is an inappropriate value of the coupling \( c_1 \). It is encouraging that our result agrees with experiment.

Another source of systematic errors in our results are \( O(\alpha_s^2) \) two-loop perturbative corrections for the renormalization factors for the NRQCD action, the \( O(\alpha) \)-improved Wilson action and the axial vector current, and the \( O(\alpha_s/(aM)^2 \) one-loop corrections in the coefficients of the NRQCD action and the axial vector current. A sizable \( O(\alpha_s^2) \) uncertainty at \( \beta = 5.7 \), diminishes to a 5\% level at weaker couplings of \( \beta = 5.9 \) and 6.1. The \( O(\alpha_s/(aM)^2 \) error, on the other hand, increases toward smaller lattice spacings, reaching \( \sim 6\% \) at \( \beta = 6.1 \). This counter increase of the error represents the limitation of lattice NRQCD. The method breaks down once the heavy quark mass becomes smaller than the inverse lattice spacing. Therefore, the validity of a lattice NRQCD calculation of \( f_B \) hinges on the existence of a window in lattice spacing over which the two errors as well as scaling violations are small.

We find that these conditions are optimally satisfied at \( \beta = 5.9 \sim 6.1 \). Pushing the simulation to larger \( \beta \) does not decrease the error; achieving better accuracy with NRQCD would require two-loop calculations to extend the window toward larger lattice spacings where the \( O(\alpha_s/(aM)^2 \) error is smaller.

Our final remark concerns a comparison with an alternative method for calculating heavy quark quantities on the lattice, the nonrelativistic interpretation of relativistic actions [3]. The advantage of this method is that a continuum extrapolation can be carried out. The simulations of Refs. [23,24,27] have shown that the \( \alpha \) dependence in the heavy-light decay constant is small for currently accessible range of \( \beta = 5.7 \sim 6.3 \) and a continuum extrapolation, with either constant or linear fit in the lattice spacing, yields the decay constants with a systematic error of about 10\%. A subtle point with this method, however, is that the \( \alpha \) dependence of systematic errors is nonlinear. Hence, strictly speaking, it is not correct to extrapolate the result with a simple linear or a quadratic function of \( \alpha \). To achieve a prediction of the \( B \) decay constant with this method, however, is that the \( \alpha \) dependence of systematic errors is nonlinear. Hence, strictly speaking, it is not correct to extrapolate the result with a simple linear or a quadratic function of \( \alpha \). To achieve a prediction of the \( B \) decay constant.

VIII. CONCLUSIONS

In this article we have presented a scaling study of the heavy-light meson decay constant using lattice NRQCD, for which the heavy-light current is improved, consistently with the action, to the one-loop order \( O(\alpha_s) \) and to \( O(\alpha_s) \) in perturbation theory. Mixings with the relevant higher dimensional operators are also taken into account. We have found the effect of the improvement to be substantial: the large \( \alpha \) dependence of \( f_B \) is almost removed. This is most apparent in the static limit where the effect is purely of \( \alpha_s \). A similar improvement is also seen for the physical \( B \) mass.

The two main sources of systematic errors in our results are \( O(\alpha_s^2) \) two-loop perturbative corrections for the renormalization factors for the NRQCD action, the \( O(\alpha) \)-improved Wilson action and the axial vector current, and the \( O(\alpha_s/(aM)^2 \) one-loop corrections in the coefficients of the NRQCD action and the axial vector current. A sizable \( O(\alpha_s^2) \) uncertainty at \( \beta = 5.7 \), diminishes to a 5\% level at weaker couplings of \( \beta = 5.9 \) and 6.1. The \( O(\alpha_s/(aM)^2 \) error, on the other hand, increases toward smaller lattice spacings, reaching \( \sim 6\% \) at \( \beta = 6.1 \). This counter increase of the error represents the limitation of lattice NRQCD. The method breaks down once the heavy quark mass becomes smaller than the inverse lattice spacing. Therefore, the validity of a lattice NRQCD calculation of \( f_B \) hinges on the existence of a window in lattice spacing over which the two errors as well as scaling violations are small.

We find that these conditions are optimally satisfied at \( \beta = 5.9 \sim 6.1 \). Pushing the simulation to larger \( \beta \) does not decrease the error; achieving better accuracy with NRQCD would require two-loop calculations to extend the window toward larger lattice spacings where the \( O(\alpha_s/(aM)^2 \) error is smaller.

Our final remark concerns a comparison with an alternative method for calculating heavy quark quantities on the lattice, the nonrelativistic interpretation of relativistic actions [3]. The advantage of this method is that a continuum extrapolation can be carried out. The simulations of Refs. [23,24,27] have shown that the \( \alpha \) dependence in the heavy-light decay constant is small for currently accessible range of \( \beta = 5.7 \sim 6.3 \) and a continuum extrapolation, with either constant or linear fit in the lattice spacing, yields the decay constants with a systematic error of about 10\%. A subtle point with this method, however, is that the \( \alpha \) dependence of systematic errors is nonlinear. Hence, strictly speaking, it is not correct to extrapolate the result with a simple linear or a quadratic function of \( \alpha \). To achieve a prediction of the \( B \) decay constant.

\begin{equation}
M_{B_s} - M_B = 25(5)(5) \text{ MeV},
\end{equation}

\begin{equation}
M_{B_s} - M_B = 28(3)(6) \text{ MeV},
\end{equation}

where we assume a 20\% systematic error for the \( O(\alpha_s) \) correction for \( c_1 \).
meson decay constant more accurate than is available, one needs to improve the action and currents so that the systematic errors at finite values of $\beta$ are further reduced. In this sense studies of $O(\alpha_s \alpha)$ improvement should be awaited. In spite of the limitations inherent in the two alternative methods, it is encouraging to see that the two approaches now yield $B$ meson decay constant in mutual agreement within 10% error in the framework of quenched QCD.
