Preliminary version: February 27, 2005

Abstract
In this paper we propose an unbiased estimator of cross-volatility (conditional covariance between two asset returns) when we must use evenly spaced data which have already been manipulated by previous-tick interpolation.

Keywords: Integrated cross volatility; Unevenly sampled observations; Previous tick interpolation; Bias correction

JEL Classification: C14; C32; C63

1 Introduction

1.1 Data generating process and observations
We consider $n$-dimensional logarithmic price $p(t) = (p_1(t), \cdots, p_n(t))'$ which follows the stochastic differential equation:

$$dp(t) = \Sigma(t) dz(t), \quad 0 \leq t \leq T$$

where $\Sigma(t)$ is an $n \times n$ matrix $[\sigma_{ij}(t)]_{i,j=1,\ldots,n}$, and $z$ is an $n \times 1$ vector of independent standard Brownian motions. We set the drift vector as 0, for the purpose of simplification.\footnote{This simplification is acceptable not only because it means an efficient market in financial economics, but also because, mathematically, the martingale component swamps the predictable portion over short time intervals.} We define the volatility matrix as
\[
\Omega \equiv \Sigma \Sigma',
\]
that is to say, cross volatility between $i$th and $j$th asset is denoted as the $ij$ element of $\Omega$:
\[
\omega_{ij}(t) = \sum_{k=1}^{n} \sigma_{ik}(t) \sigma_{jk}(t).
\]

Each $i$th asset price is observed at irregular time points $\{t_{i,k}\}_{k=0}^{N_i}$.\footnote{For the purpose of simplification, we set $t_{i,0} = 0$ and $t_{i,N_i} = T$.} We just impose the assumption on the observation points that the time intervals are small: $\lim_{N_i \to \infty} \sup_{j \geq 1} (t_{j}^{i} - t_{j-1}^{i}) = 0$. Since we concentrate on the ex post cross volatility measuring and do not make any hypothesis on the structure of the underlying probability space $\Omega$, we can construct an auxiliary probability space $X$ where we consider $\Sigma(t)$ as deterministic functions. See Malliavin and Mancino (2002). Throughout this paper, $E$ denotes the expectation on the probability space $X$.

\section{Previous-tick interpolation and realized volatility}

The raw data which are unevenly spaced, are converted to evenly spaced data in order to apply to the usual discrete time series analysis. Dacorogna, Gençay, Müller, Olsen, and Pictet (2001) introduces some interpolation methods including previous tick interpolation. When constructing $M + 1$ evenly spaced data $\{q(mT/M)\}_{j=0}^{M}$ from $\{p_i(t_{k}^{i})\}_{k=0}^{N_i}$, previous-tick interpolation is defined by the following formula.
\[
q_i \left( \frac{mT}{M} \right) = p_i \left( \max \left\{ t_k^i : t_k^i \leq mT/M \right\} \right) \tag{2.1}
\]
where \( \max A \) and \( \min A \) denote maximum and minimum elements of \( A \), respectively.

Using evenly spaced data of \( \{q_i(mT/M)\}_{m=0}^{M} \) and \( \{q_j(mT/M)\}_{m=0}^{M} \), the integrated cross volatility \( \int_{0}^{T} \omega_{ij}(t) dt \) is measured by the following estimator,

\[
\hat{\omega}_{ij}(M) = \sum_{m=1}^{M} \Delta q_i \left( \frac{mT}{M} \right) \Delta q_j \left( \frac{mT}{M} \right),
\]

(2.2)

where \( \Delta q_i(mT/M) \equiv q_i(mT/M) - q_i((m-1)T/M) \). The bias of \( \hat{\omega}_{ij}(M) \) is

\[
\sum_{m=1}^{M} \int_{t_m^-}^{t_m^+} \omega_{ij}(t) dt
\]

(2.3)

Notice that in the case of univariate volatility (\( i = j \)), for \( t_m^- = t_m^+ \), the realized volatility through previous tick interpolation is an unbiased estimator.

The variance of \( \hat{\omega}_{ij}(M) \) is

\[
\sum_{A \cap B} \left( \int \omega_{ij}(t) dt \right)^2 + \sum_{B} \int \omega_{ii}(t) dt \int \omega_{jj}(t) dt,
\]

where

\[
I(k, l) = (t_{k-1}^i, t_k^i) \cap (t_{l-1}^i, t_l^i)
\]

\[ A = \{(k, l)|I(k, l) \neq \emptyset\} \]

\[ B = \bigcup_{m=1}^{M} ((k, l)|k_{m-1} < k \leq k_m, l_{m-1} < l \leq l_m) \]

\[ k_m = \arg \max_k \{t_k^i : t_k^i \leq mT/M\} \]

\[ l_m = \arg \max_l \{t_l^i : t_l^i \leq mT/M\}. \]

See Kanatani (2004) for the calculation of it. We define an unbiased estimator by

\[
\tilde{\omega}_{ij}(M) = \sum_{m=2}^{M} \Delta^2 \tilde{q}_i \left( \frac{mT}{M} \right) \Delta^2 \tilde{q}_j \left( \frac{mT}{M} \right) - \sum_{m=2}^{M-1} \Delta \tilde{q}_i \left( \frac{mT}{M} \right) \Delta \tilde{q}_j \left( \frac{mT}{M} \right).
\]

(2.4)
where $\Delta^2 q_i(mT/M) \equiv q_i(mT/M) - q_i((m-2)T/M)$, $\{q_i(mT/M)\}_{m=1}^M = \{q_i(mT/M)|\Delta q_i(mT/M) \Delta q_j(mT/M) \neq 0\}$. The variance of $\hat{\omega}_{ij}(M)$ is

$$\sum_A \left( \int \omega_{ij}(t) \, dt \right)^2 + \sum_{B'} \int \omega_{ii}(t) \, dt \int \omega_{jj}(t) \, dt,$$

where $B' = \bigcup_{m=1}^M (\{k, l\} | k_{m-1} < k \leq k'_m, l_{m-1} < l \leq l'_m)$

$k'_m = \min\{k_m : k_m > k_{m-1}\}

l'_m = \min\{l_m : l_m > l_{m-1}\}$.

Since $(A \cap B) \subset A$ and $B \subset B'$, it is obvious that $V(\hat{\omega}_{ij}(M)) < V(\tilde{\omega}_{ij}(M))$.

### 3 Monte Carlo study

We examine the above theory through a Monte Carlo study. Without loss of generality, we set the number of assets as two. We follow the Monte Carlo design of Barucci and Renò (2002) with some modification for multivariate setting: we generate proxy for continuous observations by discretizing following stochastic differential equations with a time step of one second,

$$\begin{pmatrix} dp_1(t) \\
 dp_2(t) \end{pmatrix} = \begin{pmatrix} \sigma_{11}(t) & \sigma_{12}(t) \\
 \sigma_{21}(t) & \sigma_{22}(t) \end{pmatrix} \begin{pmatrix} dW_1(t) \\
 dW_2(t) \end{pmatrix}, 0 \leq t \leq T$$

$$d\sigma_{ij}(t) = \kappa_{ij} (\theta_{ij} - \sigma_{ij}(t)) \, dt + \gamma_{ij} dW_{ij}(t), i, j = 1, 2.$$ 

where $\kappa_{ij} = 0.01, \theta_{ij} = 0.01$, and $\gamma_{ij} = 0.001$ for any $i, j$ and $T = 60 \times 60 \times 24$ seconds. Time differences are drawn from an exponential distribution with mean 45 seconds for $p_1$ and 60 seconds for $p_2$: \(^3\)

$$F(t^i_k - t^i_{k-1}) = 1 - \exp \left\{ -\lambda_i (t^i_k - t^i_{k-1}) \right\}, i = 1, 2$$

where $F(\cdot)$ denotes a cumulative distribution function, $\lambda_1 = 1/45$ and $\lambda_2 = 1/60$.

\(^3\)Of course, our method allows the duration to be correlated or autocorrelated. See Engle and Russell (1998) for an autocorrelated duration model.
We compared the performances of realized volatility $\hat{\omega}_{ij}(M)$ and $\tilde{\omega}_{ij}(M)$. In calculations of the realized volatility of $\hat{\omega}_{ij}(M)$ and $\tilde{\omega}_{ij}(M)$, we set $M = 24, 48, 144, 288, \text{ and } 720$, corresponding to so-called daily realized volatility based on 60-min, 30-min, 10-min, 5-min and 2-min returns. We performed 300 replications.

Figure 1: Distribution of errors

![Figure 1: Distribution of errors](image)

Note: 60-min(PR): $\hat{\omega}_{12}(24)$; 30-min(PR): $\hat{\omega}_{12}(48)$; 10-min(PR): $\hat{\omega}_{12}(144)$; 5-min(PR): $\hat{\omega}_{12}(288)$; 2-min(PR): $\hat{\omega}_{12}(720)$; 60-min(BC): $\tilde{\omega}_{12}(24)$; 30-min(BC): $\tilde{\omega}_{12}(48)$; 10-min(BC): $\tilde{\omega}_{12}(144)$; 5-min(BC): $\tilde{\omega}_{12}(288)$; 2-min(BC): $\tilde{\omega}_{12}(720)$; The distribution is computed with 300 ‘daily’ replications.

Figure 1 shows the distribution of errors of $\hat{\omega}_{ij}(M)$ and $\tilde{\omega}_{ij}(M)$:

$$\hat{\omega}_{12}(M) - \int_0^T \omega_{12}(t)\,dt, \quad \text{and} \quad \tilde{\omega}_{12}(M) - \int_0^T \omega_{12}(t)\,dt,$$

respectively.

</table>

Note: Sample biases are given in parentheses.

Table 1 reports the sample MSE and bias (in parenthesis) of $\hat{\omega}_{12}(M)$ from 300 replications:

$$\frac{1}{R} \sum_{r=1}^{R} \left( \hat{\omega}_{ij}^r(M) - \int_0^T \omega_{ij}^r(t) \, dt \right)^2$$

and

$$\frac{1}{R} \sum_{r=1}^{R} \left( \tilde{\omega}_{ij}^r(M) - \int_0^T \omega_{ij}^r(t) \, dt \right),$$

where $r$ denotes the number of replications and $R = 300$, and those of $\tilde{\omega}_{12}(M)$:

$$\frac{1}{R} \sum_{r=1}^{R} \left( \tilde{\omega}_{ij}^r(M) - \int_0^T \omega_{ij}^r(t) \, dt \right)^2$$

and

$$\frac{1}{R} \sum_{r=1}^{R} \left( \tilde{\omega}_{ij}^r(M) - \int_0^T \omega_{ij}^r(t) \, dt \right).$$

We define the estimated bias by

$$\frac{1}{R} \sum_{r=1}^{R} \left( \hat{\omega}_{12}^r(M) - \tilde{\omega}_{12}^r(M) \right),$$
Estimated MSEs of $\hat{\omega}_{12}(M)$ and $\tilde{\omega}_{12}(M)$ are defined by
\[
\left( \frac{1}{R} \sum_{r=1}^{R} (\hat{\omega}_{12}^r(M) - \tilde{\omega}_{12}^r(M)) \right)^2 + \frac{1}{R} \sum_{r=1}^{R} \left( \hat{\omega}_{12}^r(M) - \frac{1}{R} \sum_{r=1}^{R} \hat{\omega}_{12}^r(M) \right)^2,
\]
and
\[
\frac{1}{R} \sum_{r=1}^{R} \left( \tilde{\omega}_{12}^r(M) - \frac{1}{R} \sum_{r=1}^{R} \tilde{\omega}_{12}^r(M) \right)^2,
\]
respectively. Table 1 also reports the estimated MSE and bias (in parenthesis) of $\hat{\omega}_{12}(M)$ and $\tilde{\omega}_{12}(M)$ from 300 replications.

Under our simulation design, the correlation between the 1st and 2nd asset is on average positive: $\omega_{12}(t)$ varies around a positive mean of 0.0002 because
\[
\omega_{12}(t) = \sigma_{11}(t)\sigma_{21}(t) + \sigma_{12}(t)\sigma_{22}(t)
\]
and each $\sigma_{ij}$ has the mean of 0.01. As expected from the bias (2.3), the shorter the interpolation time intervals is, the more downward biased the previous tick interpolation realized cross volatility $\hat{\omega}_{12}$ is.
