(Received 6 May 2004; published 5 October 2004)

Renormalization constants (Z-factors) of vector and axial-vector currents are determined nonperturbatively in quenched QCD for a renormalization group improved gauge action and a tadpole-improved clover quark action using the Schrödinger functional method. Nonperturbative values of Z-factors turn out to be smaller than 1-loop perturbative values by \(O(15\%)\) at a lattice spacing of \(a^{-1} \approx 1\) GeV. The pseudoscalar and vector meson decay constants calculated with the nonperturbative Z-factors show a much better scaling behavior compared to previous results obtained with tadpole-improved one-loop Z-factors. In particular, the nonperturbative Z-factors normalized at infinite physical volume show that the scaling violations of the decay constants are within about 10% up to the lattice spacing \(a^{-1} \sim 1\) GeV. The continuum estimates obtained from data in the range \(a^{-1} \sim 1-2\) GeV agree with those determined from finer lattices \((a^{-1} \sim 2-4\) GeV\) with the standard action.

I. INTRODUCTION

Reliable prediction of physical quantities from lattice QCD calculations requires a good control of scaling violations. For this purpose, several improved actions have been tested and applied to large scale systematic simulations. For most physical quantities, such as quark masses and hadronic matrix elements, one has to calculate in addition renormalization constants (Z-factors). Nonperturbative methods to determine various Z-factors have been developed and utilized for several actions.

The CP-PACS collaboration carried out systematic simulations for two-flavor full QCD [1] using a renormalization group (RG) improved gauge action [2] and a tadpole-improved [3] clover quark action [4] and reported results for the spectrum, quark masses and meson decay constants. Since nonperturbative Z-factors were not available for this action combination, the analysis had to rely on one-loop perturbative values. The result showed that the meson decay constants in both quenched and full QCD suffer from large scaling violations at \(a^{-1} \sim 1-2\) GeV which hinder continuum extrapolations.

As a first step toward a systematic study of nonperturbative renormalization for this action, we apply the Schrödinger functional (SF) method [5–8] to calculations of Z-factors for vector (\(Z_V\)) and axial-vector (\(Z_A\)) currents in quenched QCD with the same improved action. The SF method has been applied to the nonperturbatively \(O(a)\) improved Wilson action. In contrast, our action combination has \(O(a^4)\) error, since the coefficient of the clover term is determined by tadpole-improved perturbation theory to one-loop order. Therefore our study involves an examination whether the SF method successfully works for this action.

In the SF method, Z-factors are determined at various couplings for a fixed physical size \(L\). In this case, the Z-factors contain terms of \(O(a^2L)\) in addition to that of \(O(\alpha\Lambda)\). We expect that one can remove the \(O(a^4/L)\) terms by taking the infinite volume limit. We calculate Z-factors both at a finite fixed physical volume and at the
infinite volume and compare the scaling properties of decay constants with these two choices of $Z$-factors.

When we calculate $Z$-factors for large couplings and on large lattices, we encounter “exceptional configurations” for which observables take abnormally large values. We estimate systematic uncertainties due to such configurations, propagate them to systematic error estimations of decay constants, and argue that they do not alter our conclusions on scaling properties.

The organization of this paper is as follows. In Sec. II we describe calculation method focusing on features of applying the SF method to the RG-improved action. Details of the analysis for $Z_V$ and $Z_A$ are given in Sec. III. With these $Z$-factors, we study the scaling behavior of decay constants of vector ($f_{Cejj^2}$) and pseudoscalar ($f_{Cejj^3}$) mesons in Sec. IV. Sec. V is devoted to conclusions. Parts of this work have already been reported in Refs. [9,10].

II. CALCULATION METHOD

A. Action and Currents

The RG-improved gauge action we employ has the form

$$S_g = \frac{\beta}{6} \left\{ c_0 \sum_{x,\mu,\nu} U_{\mu,\nu}(x) + c_1 \sum_{x,\mu,\nu} U_{R,\mu,\nu}(x) \right\},$$

(1)

where $\beta = 6/g^2$ with the bare coupling constant $g$, and $U_p$ ($U_R$) is the trace of the product of link variables around a plaquette (6-link rectangular loop). In a sum over loops, each oriented loop appears once. The coefficients $c_1 = -0.331$ and $c_0 = 1 - 8c_1 = 3.648$ are fixed by an approximate RG analysis [2].

The clover quark action [4] is defined by

$$S_q = \sum_{x,y} \overline{\psi}(x) D_{x,y} \psi(y),$$

(2)

$$D_{x,y} = \delta_{x,y} - c \sum_\mu \left\{ (1 - \gamma_\mu) U_{x,\mu} \delta_{x+\hat{\mu},y} + (1 - \gamma_\mu \gamma_4) U_{x,\mu} \delta_{x+\hat{\mu},y} \delta_{x,\mu^{'},y} \right\} - \delta_{x,y} c_{SW} \kappa \sum_{\mu < \nu} \sigma_{\mu,\nu} F_{\mu,\nu},$$

(3)

where $\kappa$ is the hopping parameter and $F_{\mu,\nu}$ is a lattice discretization of the field strength. For the clover coefficient $c_{SW}$, we adopt a tadpole-improved value with one-loop estimate of the plaquette $\langle W^{1\times 1} \rangle = \frac{1}{3} \langle U_{p,\mu,\nu} \rangle$ given by

$$c_{SW} = \langle W^{1\times 1} \rangle^{-3/4} = (1 - 0.8412/\beta)^{-3/4},$$

(4)

since we use the one-loop value of the plaquette reproduces measured values well.

For $Z_V$, we investigate the vector Ward identity of the unimproved current $V_{\mu}^{\mu}$ since the particular SF setup we use yields the same value of $Z_V$ for improved and unimproved currents. On the other hand, we study an improved current for $Z_A$ defined by

$$(A_{\mu}^{(p)})(x) = A_{\mu}^{(p)}(x) + ac_{SW} \frac{1}{2} (\partial_{\mu}^a + \partial_{\mu}^p) P^i(x),$$

(5)

where $\partial_{\mu}^a$ and $\partial_{\mu}^p$ are lattice forward and backward derivatives and $P^i(x)$ is the pseudoscalar density. We use the one-loop value for the improvement coefficient $c_A = -0.0038g^2$ [11].

B. Implementation for RG-Improved Action

We follow the SF method of Ref. [8] for the RG-improved gauge action. Taking an $L^3 \times T$ lattice, we impose the periodic boundary condition in the spatial directions and the Dirichlet boundary condition in the temporal direction.

The boundary counter terms for the RG-improved action are determined [12] so that the classical field equations are satisfied. The total action reads

$$S_g = \frac{\beta}{6} \sum_x \sum_{x=0}^T \left\{ c_0 \sum_{\mu,\nu} w_{\mu,\nu}^p(x_4) U_{p,\mu,\nu}(x) ight\},$$

(6)

with the weight factors $w_{\mu,\nu}^p(x_4)$ and $w_{\mu,\nu}^R(x_4)$ given by

$$w_{\mu,\nu}^p(x_4) = \begin{cases} c_t & (x_4 = 0 \text{ or } x_4 = T - a) \text{ and } (\mu = 4 \text{ or } \nu = 4) \\ 0 & x_4 = T \text{ and } (\mu = 4 \text{ or } \nu = 4) \\ \frac{1}{2} c_s & (x_4 = 0 \text{ or } x_4 = T) \text{ and } (\mu \neq 4 \text{ and } \nu \neq 4) \\ 1 & \text{otherwise} \end{cases}$$

(7)
We take the tree-level value of \( c_s = c_t = 1 \). (One-loop values of \( c_s \) and \( c_t \) [13] were not known when we started this work.) Boundary counter terms are not included for the clover quark action. In other words, the boundary coefficients \( \tilde{c}_s \) and \( \tilde{c}_t \) of Ref. [8] are set to the tree-level values, \( \tilde{c}_s = \tilde{c}_t = 1 \).

C. Details of Calculation Method

We calculate \( Z \)-factors for the range \( \beta = 8.0 - 2.2 \). The smallest value \( \beta = 2.2 \) is chosen to lie in the range \( \beta = 2.575 - 2.184 \) (inverse lattice spacing \( \alpha^{-1} = 1 - 2 \) GeV) where data for \( f_P \) and \( f_A \) exist [1]. Simulations are made with a 5-hit pseudo-heat-bath algorithm mixed with an over-relaxation algorithm in the ratio of 1:4. We analyze 200 – 20000 configurations separated by 100 sweeps each. The lattice geometry is set to \( T = 2L \) for both \( Z_V \) and \( Z_A \). At each \( \beta \), \( Z \)-factors are determined for at least two lattice sizes in order to interpolate or extrapolate them to a fixed physical volume. Lattice size and number of analyzed configurations are listed in Table I.

Calculations of \( Z \)-factors are carried out at zero quark mass, where the quark mass \( m_q \) is defined by the PCAC relation \( \partial_\mu A_\mu^a = 2m_q P^a \) in the continuum notation. The actual procedure to measure \( m_q \) is the same as in Ref. [7]. We define a time-dependent quark mass by

\[
m_q(x_4) = \frac{1}{2f_P(x_4)} (\delta_0^a + \delta_0) f_A(x_4) + c_A a\delta_0^a \delta_0 f_P(x_4),
\]

where \( f_A \) is the axial-vector and pseudoscalar correlator and \( f_P \) is the pseudoscalar and pseudoscalar correlator. The quark mass \( m_q \) is defined by an average of \( m_q(x_4) \) over a range of time slices around \( x_4 = T/2 \);

\[
m_q = \frac{1}{2n+1} \sum_{t \rightarrow -n} m_q \left( \frac{T}{2} + t \right),
\]

where \( n \) defines the range and depends on simulation parameters.

\( Z \)-factors are determined from correlators of pseudoscalar operators \( P^a \) and \( P^a \) at the boundaries and/or currents \( V_\mu^a \) and \( (A_\mu)^a \) at a finite time slice. We employ the notations defined by

\[
f_1 = -\frac{1}{3L^6} (P^a P^a),
\]

\[
f_2(x_4) = \frac{\alpha^3}{6L^6} \sum_{x} i\epsilon^{abc} \langle P^a V_0^b(x) P^c \rangle.
\]

</table>
Reproduce the measured values well.

\[
f_{AA}(x_4, y_4) = \frac{a^6}{6L^6} \sum_{x,y} \epsilon^{abc} \epsilon^{cde} (P^{cd}(A)_0(x)(A)_0(y)P^{e}).
\] (13)

Renormalization constants are then extracted from

\[
Z_V = \frac{f_1}{f_V(\zeta)};
\] (14)

\[
Z_A = \sqrt{\frac{f_1}{f_{AA}(\frac{53}{8})}}.
\] (15)

The lattice spacing necessary to set the physical size is determined from the string tension $\sqrt{\sigma} = 440$ MeV. We fit values of $a\sqrt{\sigma}$ [1,14] to a fitting form [15]

\[
(a\sqrt{\sigma})(\beta) = f(\beta)(1 + c_2 \hat{a}^2(\beta) + c_4 \hat{a}^4(\beta) + \cdots)/c_0.
\]

where $f(\beta)$ is the two-loop scaling function of the SU(3) gauge theory, $c_i$'s are parameters to describe deviation from the two-loop scaling, and $\beta_1$ is a reference point. Choosing $\beta_1 = 2.4$, the parameters

\[
c_0 = 0.5443(97), \quad c_2 = 0.390(38), \quad c_4 = 0.049(12)
\] (17)

reproduce the measured values well.

III. RENORMALIZATION CONSTANTS

A. Results at Simulation Points

Calculations of $Z$-factors do not present any difficulty from $\beta = 8.0$ down to 2.6 for all lattice sizes, and at $\beta = 2.4$ and 2.2 on a small lattice of $4^3 \times 8$. For a larger $8^3 \times 16$ lattice at $\beta = 2.4$ and 2.2, however, we encounter “exceptional configurations.” Deferring discussions of this issue, let us first summarize results for the nonexceptional case.

We first determine $\kappa_c$ for each $\beta$ and $L/a$. For this purpose simulations are carried out at several values of $\kappa$ around an estimated $\kappa_c$ in which $m_q$ is determined by Eq. (10); we employ the fitting range given by $n = 0$ for $L/a = 4$ lattices, $n = 1$ for $L/a = 8$ lattices at $\beta = 2.4$ and 2.2, and $n = 2$ for $L/a = 8$ at other values of $\beta$ and $L/a = 16$ lattices. We determine $\kappa_c$ by a linear fit in $\kappa$ as illustrated in Fig. 1 for an $8^3 \times 16$ lattice at $\beta = 2.6$. 

![Figure 1](image1.png)

**FIG. 1.** $m_q$ versus $\kappa$ at $\beta = 2.6$ on an $8^3 \times 16$ lattice. Filled symbols show measured points. The open symbol represents $\kappa_c$.

![Figure 2](image2.png)

**FIG. 2.** Effective quark mass $m_q(x_4)$ at $\beta = 2.6$ on an $8^3 \times 16$ lattice. Horizontal solid lines represent fitting range, and fitted value and error.

![Figure 3](image3.png)

**FIG. 3.** $Z_V$ as a function of time slice at $\beta = 3.125$ on a $16^3 \times 32$ lattice. Horizontal dashed lines represent $Z_V$ at $x_4 = T/2 = 16$.
Results for $\kappa_c$ are given in Table I. When we perform simulations for $Z$-factors at $\kappa_c$, $m_q$ is also calculated for confirmation. A typical result for the effective quark mass $m_q$ is shown in Fig. 2. It exhibits a reasonable plateau. Values of $m_q$ at $\kappa_c$ are given in the fourth column of Table I. They are consistent with zero within an accuracy of $10^{-3}$ at worst. Since $\kappa_c$ is tuned well, errors of $\kappa_c$ are not taken into account in the error estimation of $Z$-factors.

Figs. 3 and 4 show typical plots of $Z_V$ and $Z_A$ as a function of time slice. We observe good plateaux for all cases, except for a small temporal lattice size of $L/a = 8$ at strong coupling of $\beta = 2.4$ and 2.2. We thus find that the SF method works successfully for our action, albeit there are $O(a^4)$ errors rather than $O(a^2)$ errors. Results for $Z$-factors at simulation points are given in Table I.

We now discuss the issue of “exceptional configurations.” Among our parameter sets, anomalously large values appear in the ensemble of hadron correlators on an $8^3 \times 16$ lattice at $\beta = 2.4$ and 2.2. We illustrate the situation in Fig. 5, where we plot the time history of $f_A$ and $f_p$ at $\beta = 2.4$. No large spikes appear for larger $\beta$ on the same size lattice, as shown in Fig. 6 for data at $\beta = 2.6$. Note that a much finer vertical scale is employed in the latter figure. Large spikes appear also in the ensembles of $f_1, f_V$ and $f_A$, necessary for evaluating $Z$-factors. Such exceptional configurations make it difficult to determine $m_q, \kappa_c$ and $Z$-factors precisely.
We suspect that the spikes are caused by the appearance of very small or even negative eigenvalues of the Dirac operator toward strong coupling. Such eigenvalues would be suppressed in full QCD by the quark determinant, and in this sense we expect exceptional configurations to be an artifact of quenched QCD. In quenched QCD, however, “exceptional configurations” cannot be distinguished from “normal” ones on some rigorous basis. In fact, histograms of f’s have a long tail toward very large values as shown in Fig. 7. We then adopt the strategy of estimating Z-factors by removing from the ensemble average configurations having values above some cutoff. The uncertainties associated with this procedure are estimated by varying the cutoff, and will be propagated to systematic errors of Z-factors at fixed physical volume. Detailed description of this procedure will be given in Sec. III C.

B. Z-factors at Fixed Physical Volume

We plot Z_V and Z_A determined for various sizes and β in Figs. 8 and 9, respectively, as a function of a/L. There are three or four data points at β = 8.0 and 2.8 for Z_V, and at β = 2.8 for Z_A. These data show a linear behavior in a/L, which is consistent with the expectation that Z-factors for our action have O(a g^4 / L) errors. Therefore we adopt a linear ansatz to extrapolate or interpolate Z-factors to the physical volume of L = 0.8 fm (normalized at β = 2.6 and L/a = 8) and to L = ∞, as shown in these figures. We denote Z-factors at a fixed physical volume as Z^{SF,L=0.8 fm}_{VA} and Z^{SF,L=∞}_{VA}. Numerical values are given in Table II.

In Fig. 10 we plot Z_V as a function of g^2. Making a Padé fit, we obtain

\[ Z^{SF,L=0.8 \text{ fm}}_V = \frac{1 - 0.302 225 g^2 + 0.011 034 g^4}{1 - 0.239 431 g^2}, \]

\[ Z^{SF,L=∞}_V = \frac{1 - 0.365 802 g^2 + 0.015 016 g^4}{1 - 0.303 008 g^2}, \]

where we have imposed a constraint that the Padé fits reproduce the one-loop perturbative result Z_V = 1 − 0.062 794 g^2 [16] up to O(g^4).

The range of coupling where there are data for the vector meson decay constant is marked by the two vertical dashed lines in Fig. 10. Over this range, Z^{SF,L=∞}_V becomes increasingly smaller (by about 8%–21%) compared to the one-loop value (dashed line) and the tadpole-improved value (crosses). We also observe that Z_V exhibits a sizable volume dependence toward strong coupling, e.g., for β = 2.8. This will have an important consequence on the scaling property of f_ρ as discussed in Sec. IV.

Another method to estimate $Z_V$ nonperturbatively [17] utilizes the nonrenormalizability of the conserved vector current

$$V_i^C(x) = \frac{1}{2} [\bar{\psi}(x + a \hat{\mu}) U_{x,\mu}^\dagger (\gamma_i + 1) \psi(x) + \bar{\psi}(x) U_{x,\mu} (\gamma_i - 1) \psi(x + a \hat{\mu})],$$  

and defines

$$Z_V^{\text{NPC}} = \lim_{x \to \infty} \sum_x \langle 0 | V_i^C(x, x_4) V_i | 0 \rangle.$$  

(21)

Results for $Z_V^{\text{NPC}}$ obtained for our action combination [1] are also overlaid in Fig. 10 (open diamonds). They are much smaller than those from the SF method. We interpret that the large difference originates from large $O(a)$ errors in $Z_V^{\text{NPC}}$. From the viewpoint of $O(a)$ improvement of operators, the divergence of a tensor operator $\partial_i C_{\gamma j} T_{\gamma j}^C$ should be added to both the local current $V_i$ and the conserved current $V_i^C$ [18]. However, the improvement operator $\sum_j \partial_j T_{0j}$, necessary for $V_0$ in the SF scheme, automatically drops out since it is a spatial total divergence. In other words, $Z_V$ from the SF method is $O(a)$ improved, whereas $Z_V^{\text{NPC}}$ is not.

In Fig. 11, we plot results for $Z_A$ and Padé fits which read

$$Z_A^{\text{SF, } L=0.8 \text{ fm}} = \frac{1 - 0.277 576 g^2 + 0.008 669 g^4}{1 - 0.220 946 g^2},$$  

$$Z_A^{\text{SF, } L=\infty} = \frac{1 - 0.334 232 g^2 + 0.011 710 g^4}{1 - 0.277 602 g^2}.$$  

(22)

(23)

In the Padé fits, we use a constraint from one-loop perturbation theory that $Z_A^\text{TP} = 1 - 0.056 630 g^2 + O(g^4)$ [16]. We observe that $Z_A^{\text{SF, } L=\infty}$ for the range we have data for $f_\pi$ are smaller than the tadpole-improved value by $6\%–14\%$.

C. Systematic Error from Exceptional Configurations

Exceptional configurations affect $Z$-factors in two ways, first by changing the value of $m_q$ and hence of $\kappa_\epsilon$, and secondly by directly affecting the value of $Z$-factors themselves. Hence, in order to estimate the uncertainties

FIG. 10. Comparison of $Z_V$ from tadpole-improved perturbation theory and those from SF method normalized at $L = 0.8$ fm and $L = \infty$. $Z_V^{\text{NPC}}$ are determined with the conserved current. Padé fits and error are also given for $Z_V$ from the SF method. Vertical dashed lines represent the range we have data for decay constants.

FIG. 11. Comparison of $Z_A$ determined by various methods. Symbols are the same as in Fig. 10.

FIG. 12. $m_q$ vs $f_{P, \text{cut}}$ at $\kappa_\epsilon$ on an $8^3 \times 16$ lattice at $\beta = 2.4$. 

074502-7
of $Z$-factors due to exceptional configurations at large couplings, we investigate how $m_q$ and $Z$-factors change if we discard configurations having values of relevant correlators larger than some cutoff.

Figure 12 shows this test for $m_q$ at $\beta = 2.4$ for which a cutoff is set for the value of $f_P$. As the cutoff $f_{P,\text{cut}}$ is increased, $m_q$ gradually decreases, becomes almost stable around $f_{P,\text{cut}}=300$ and then the error of $m_q$ becomes large. With this observation in mind, we have estimated $\kappa_c$ as the point where $m_q$ for $f_{P,\text{cut}}=300$ is consistent with zero, as shown in Fig. 12. The uncertainty in $m_q$ at $\kappa_c$ is estimated by varying $f_{P,\text{cut}}$ from 200 to 1000 and turns out to be $+0.00028 > m_q > -0.00182$. The same procedure at $\beta = 2.2$ with $f_{P,\text{cut}}=500$ gives the uncertainty $+0.00344 > m_q > -0.00170$. We note that the number of configurations discarded is 37 (191) of the total of 10 000 (20 000) configurations at $\beta = 2.4$ (2.2).

The uncertainty of $m_q$ is translated into uncertainties of $Z$-factors. To do this, we carry out two additional simulations at $\kappa$’s slightly above and below $\kappa_c$. Figs. 13 and 14 show how $Z$-factors depend on $m_q$; $Z_V$ is very stable against variation of $m_q$, while $Z_A$ shows a more prominent dependence. We fit the $m_q$ dependence of the $Z$-factors by a linear function, and uncertainties of $Z$-factors are estimated by the difference of the central value and the maximum/minimum value for the range of error of $m_q$. The uncertainties are given in Table III under the column $\delta Z^{\text{m}_{q}}$.

We also estimate uncertainties in the statistical averaging of $Z$-factors themselves by varying the cutoff of $f_V$. Figure 15 shows the ensemble average of $f_1$ and $f_V$ together with $Z_V$ as a function of the cutoff $f_{V,\text{cut}}$. Though both $f_1$ and $f_V$ increase as $f_{V,\text{cut}}$ increases, $f_1$ and $f_V$ are highly and positively correlated. We determine the central value from $f_{V,\text{cut}}=5.0$ and estimate errors by varying $f_{V,\text{cut}}$ from 2.0 to 10.0. Figure 16 shows a similar test for $Z_A$. The cutoff dependence is more conspicuous than for $Z_V$. Uncertainties thus estimated are listed in Table III under the column $\delta Z^{\text{except}}$. Note that we discard 47 (221) configurations at $\beta = 2.4$ (2.2).

The two uncertainties $\delta Z^{m_{q}}$ and $\delta Z^{\text{except}}$ are simply added to estimate the total uncertainty $\delta Z$ for $L/a = 8$ lattices. We then propagate them to uncertainties of $Z$-factors at fixed physical volume, listed in Table III. Uncertainties at $L = 0.8$ fm are smaller than those on $L/a = 8$ lattices, because the physical size is located between $L/a = 8$ and $L/a = 4$ lattices. Uncertainties of $Z$-factors at $L = \infty$, enlarged by extrapolations, are larger than the statistical error $\delta Z^{\text{stat},L=\infty}$.

### D. Z-factors at Simulation Points for Meson Decay Constants

For discussions of scaling properties of meson decay constants, we need $Z$-factors at $\beta$ values where raw data of $f_\rho$ and $f_\pi$ are taken. We evaluate them using the Padé fits obtained in Sec. III B together with the estimates of uncertainties from exceptional configurations.

For the latter purpose, we repeat Padé fits varying the $Z$-factor at $\beta = 2.4$ within the range of its uncertainty,
calculate the Z-factor at a target \( \beta \) value, and take the difference between this value and the central value as an estimate of the systematic error from exceptional configurations at \( \beta = 2.4 \). The systematic error from those at \( \beta = 2.2 \) is estimated similarly and added linearly to obtain the total systematic error.

Our final results for Z-factors at the simulation points for meson decay constants are listed in Table IV. The systematic errors in \( Z_{V}^{SF,L=\infty} \) and \( Z_{A}^{SF,L=\infty} \) are comparable to the statistical ones and within at most two \( \sigma \). The ratio of systematic errors to statistical errors in the table is slightly smaller than the ratio at simulation points for Z-factors, \( \beta = 2.4 \) and 2.2, because the Padé fits are stabilized with data at \( \beta \geq 2.6 \) where no exceptional configurations appear. In the table, we reproduce the one-loop tadpole-improved values \( Z_{V,A}^{TP} \) together with \( Z_{V,A}^{NPC} \) for comparison.

### IV. SCALING PROPERTIES OF MESON DECAY CONSTANTS

We investigate the scaling property of \( f_{\rho} \), combining the unrenormalized values of \( f_{\rho} \) [1] and four different choices of \( Z_{V} \); 1) one-loop tadpole-improved value, \( Z_{V}^{TP} \), 2) values determined by the SF method for \( L = 0.8 \) fm, \( Z_{V}^{SF,L=0.8 \text{ fm}} \), 3) those at \( L = \infty \), \( Z_{V}^{SF,L=\infty} \), and 4) \( Z_{V}^{NPC} \) in Eq. (21) defined by the conserved current. The unrenormalized \( f_{\rho} \) was determined in Ref. [1] for unimproved current. Hence, the renormalized \( f_{\rho} \) has \( O(\alpha g^{2}) \) error.

Numerical values of the renormalized \( f_{\rho} \) are listed in Table V. Statistical errors in the unrenormalized \( f_{\rho} \) and in \( Z_{V}^{SF,L=0.8 \text{ fm}} \) or \( Z_{V}^{SF,L=\infty} \) are added in quadrature, while systematic uncertainties for the latter are simply propa-

gated to that of the renormalized \( f_\rho \). Fortunately, systematic uncertainties from exceptional configurations are sufficiently small. They are at most 0.4\( \sigma \) of the statistical errors and do not affect the conclusions below. Therefore we ignore systematic uncertainties in the following discussions.

Figure 17 presents the results for \( f_\rho \) as a function of \( a \). Open circles are the previous result obtained with tadpole-improved one-loop Z-factor, which exhibits a sizable scaling violation. If instead one uses the nonperturbative \( Z_V \) for \( L = \infty \), we observe a much better scaling behavior (filled triangles). The Z-factor evaluated for \( L = 0.8 \) fm lies in between the two results (stars).

We find this result very encouraging; it shows that an apparent large scaling violation seen with the use of \( Z_V \) is largely due to neglecting higher order contributions in the Z-factor, and that inherent \( O(a) \) errors in the vector decay constant are small even up to a large lattice spacing of \( a^{-1} \sim 1 \) GeV.

We extrapolate \( f_\rho \) with \( Z_V^{SF, L=\infty} \) to the continuum limit linearly in \( a \). The value in the continuum limit \( f_\rho = 201.7(2.0) \) MeV turns out to be consistent with that \( f_\rho = 205.7(6.6) \) MeV from a high precision simulation with the standard action [19].

We note that a relatively large scaling violation is observed for \( f_\rho \) with \( Z_V^{NPC} \) (open diamonds). Since \( f_\rho \) with \( Z_V^{NPC} \) is nothing but the decay constant determined from the conserved current in Eq. (20), we suspect that \( O(a) \) large scaling violation exists in the conserved current.

The scaling property of \( f_\pi \) is investigated in a similar manner. We note that the unrenormalized \( f_\pi \) in Ref. [1] was determined for the improved current using a tadpole-

FIG. 17. \( f_\rho \) versus \( a \) with various choices of \( Z_V \). Values for our improved action with \( Z_V^{SF} \) and \( Z_V^{NPC} \) are taken from Ref. [1]. Values for the standard action [19] are determined with Z-factors from the conserved current. Diamond at \( a = 0 \) represents the experimental value.

FIG. 18. \( f_\pi \) versus \( a \) with various choices of \( Z_A \). Symbols are the same as in Fig. 17, though \( f_\pi \) from the standard action is determined with \( Z_A^{TP} \).
improved one-loop value of $c_A$ with $\overline{\text{MS}}$ coupling, whereas $Z$-factors in this work employ $c_A$ with bare coupling. The difference in the renormalized $f_\pi$ arising from the difference of $c_A$ remains $O(a g^4)$.

Figure 18 shows $f_\pi$ versus $a$. In this figure, we have not included the systematic uncertainty since, being smaller than statistical one, it does not alter the conclusions below. Numerical values are listed in Table V. The conclusions on the scaling behavior are similar to those of $f_\rho$. Employing $Z^{s_f, L=\infty}_A$, which includes terms to all orders in $g^2$ and does not have $O(a g^4/L)$ error, the scaling behavior turns out to be better than previous results with tadpole-improved one-loop $Z$-factor indicated. Making a linear continuum extrapolation, we obtain a value $f_\pi = 123.3(8.7)$ MeV consistent with that $f_\pi = 120.0(5.7)$ MeV calculated with the standard action at significantly weaker couplings (open squares).

V. CONCLUSIONS

The Schrödinger functional method has been applied to calculations of the vector and axial-vector renormalization constants for the combination of a RG-improved gauge action and a tadpole-improved clover quark action. With the $Z$-factors determined nonperturbatively, an apparent large scaling violation in the range of lattice spacing $a^{-1} = 1 - 2$ GeV in the meson decay constants previously observed with the one-loop perturbative $Z$-factors is significantly reduced. We conclude that the improvement attempted with the gluon and quark actions employed in the present work is effective for the meson decay constants as well.

We find that scaling of decay constants is best when one uses $Z$-factors normalized at infinite volume. This suggests that removing $O(a g^4/L)$ error in $Z$-factors by the limiting procedure $L \to \infty$ is important for actions with $O(a g^4)$ error.

The nonperturbative $Z$-factors have enabled us to determine values in the continuum limit of decay constants. We may expect that other hadronic matrix elements are also reliably extracted from lattice spacings much coarser than $a^{-1} = 2$ GeV for our action combination if one uses $Z$-factors determined by the Schrödinger functional method.

Finally we recall that a large scaling violation for the meson decay constants has been observed also in two-flavor full QCD with the same action combination of quenched QCD considered in this article. A nonperturbative determination of $Z$-factors will therefore be interesting to pursue for this case. Exceptional configurations are expected to be absent in full QCD. Therefore the Schrödinger functional calculation would be more straightforward. Work in this direction is in progress.
