Abstract

Background: Inflammatory processes could underlie mood disorders. Matrix metalloproteinases (MMPs) and tissue inhibitors of MMPs (TIMP) are inflammation-related molecules. The current study sought an association between mood disorders and systemic levels of MMPs and TIMPs.

Methods: Serum was obtained from patients with mood disorders (n = 21) and patients with schizophrenia (n = 13) scheduled to undergo electroconvulsive therapy. Serum was also obtained from healthy controls (n = 40). Clinical symptoms were assessed by the Hamilton Rating Score for Depression and the Brief Psychiatric Rating Scale. Serum levels of MMPs and TIMPs were quantified by ELISA.

Results: The serum levels of MMP-2 in mood disorder patients, but not in schizophrenia patients, prior to the first electroconvulsive therapy session (baseline) was significantly lower than that of healthy controls. At baseline, levels of MMP-9 and TIMP-2, -1 were not different between patients with mood disorder and schizophrenia and healthy controls. After a course of electroconvulsive therapy, MMP-2 levels were significantly increased in mood disorder patients, but MMP-9 levels were significantly decreased in both mood disorder and schizophrenia patients. In mood disorder patients, there was a significant negative correlation between depressive symptoms and serum levels of MMP-2 and a positive correlation between depressive symptoms and MMP-9. In addition, alterations of serum levels of MMP-2 and MMP-9 were significantly correlated each other and were associated with certain depressive symptoms.

Conclusion: A change in inflammatory homeostasis, as indicated by MMP-2 and MMP-9, could be related to mood disorders, and these markers appear to be sensitive to electroconvulsive therapy.

Keywords: MMP-2, MMP-9, mood disorders, schizophrenia, electroconvulsive therapy
Introduction

Matrix metalloproteinases (MMPs) are zinc-dependent proteases that are involved not only in the degradation and remodeling of the extracellular matrix but also in processing bioactive molecules, including cell surface receptors, neurotrophic factors, chemokines, and cytokines (Kim and Joh, 2012). MMPs are indispensable enzymes for various physiological processes such as embryogenesis, morphogenesis, tissue reconstruction, and regulation of inflammatory processes under a variety of conditions (Nissinen and Kahari, 2014). MMPs belong to a family of more than 25 enzymes, and each has its own activating cascade with MMP-2 and MMP-9 at the core. Among MMPs, gelatinases, including MMP-2 and MMP-9, are similar in structure and are able to enzymatically process various substrates of the extracellular matrix, such as gelatin, collagen I and collagen IV (Sbardella et al., 2012). Constitutively expressed in most cell types, MMP-2 has a prohomeostatic property, whereas MMP-9 is expressed at low levels in most cell types but is highly responsive to stimulation and has proinflammatory properties (Van den Steen et al., 2002; Sbardella et al., 2012).

These enzymes are also known to be related to pathological processes such as cancer, neurodegenerative disorders, arthritis, and cardiovascular diseases (Sbardella et al., 2012). In the central nervous system, MMPs play important roles in synaptogenesis, synaptic plasticity, and long-term potentiation (Ethell and Ethell, 2007). In contrast, there are limited studies of the role of MMPs in psychiatric disorders.

The MMPs are endogenously inhibited by the tissue inhibitors of MMPs (TIMPs). In humans, 4 TIMP species have been reported. Of these, the C-terminal domain of TIMP-1 and TIMP-2 binds to the hemopexin of the proenzymes of MMP-9 and MMP-2, respectively (Carlo, 2014). This indicates that TIMP-1 and TIMP-2 are major individual inhibitors of MMP-9 and MMP-2 (Goldberg et al., 1992).

Mood disorders (MDs) have been recognized as having a strong association with chronic inflammatory states (Rosenblat et al., 2014). In depression, fatigue and somatic symptoms such as gastrointestinal symptoms, autonomic symptoms, and flu-like malaise are significantly associated with signs of an activated inflammatory pathway (Maes et al., 2012). Several studies have reported an association between depressive symptoms and state-dependent elevated levels of inflammatory markers, such as interleukin-1 beta, interleukin-6, and tumor necrosis factor-alpha (Felger and Lotrich, 2013; Rosenblat et al., 2014). MMPs process cytokines, which leads to alterations of their activity (Van Lint and Libert, 2007). At the same time, the expression of MMPs, MMP-9 in particular, is regulated by cytokines (Harkness et al., 2000). This indicates that cytokines and MMPs regulate each other in a bidirectional manner.

The current study sought to find an association between MD and inflammation-related markers. The main MMPs, MMP-2 and MMP-9, and their inhibitors, TIMP-2 and TIMP-1, were quantified in patients with MD. First, serum levels of MMP-2, MMP-9, TIMP-2, and TIMP-1 from patients with MD who had depressive episodes and were eligible for electroconvulsive therapy (ECT) were compared with healthy controls and patients with schizophrenia-spectrum disorders (SCZ), who also had psychotic episodes and were also eligible for ECT. Serum levels of MMP and TIMP were then compared before and after a course of ECT in patients with MD and SCZ. Finally, an association between serum levels of MMPs and TIMPs with clinical symptoms in patients with MD and SCZ was determined.
asymptomatic or the attending psychiatrist determined that the patient had obtained the maximum benefit within 3 to 15 sessions. After the purpose and the ECT procedure were described in detail, written informed consent was obtained from patients or caregivers of patients prior to initiating ECT.

Most of patients with MD (20/21 patients) received antidepressant pharmacotherapy before ECT: duloxetine (20–60 mg/d; n = 6), mirtazapine (15–45 mg/d; n = 8), paroxetine (20–40 mg/d; n = 4), sertraline (25–100 mg/d; n = 2), mianserin (10–60 mg/d; n = 5), trazodone (25–75 mg/d; n = 3), imipramine (50 mg/d; n = 1), or nortriptyline (100 mg/d; n = 2). Nine subjects were on a stable dose of antidepressant during ECT, 8 subjects had antidepressant dosage decreased during the course of ECT, and 3 subjects had antidepressant dosage increased during the course of ECT. One patient did not receive any antidepressants while undergoing the course of ECT. Eleven of 21 patients with MD also took an antipsychotic medication (either olanzapine or quetiapine) before the course of ECT to control either psychomotor agitation or psychotic symptoms.

Eleven of 13 patients with SCZ received antipsychotic pharmacotherapy before the course of ECT: risperidone (1.5–12 mg/d; n = 7), olanzapine (10–20 mg/d; n = 4), quetiapine (300–675 mg/d; n = 4), zotepine (150–400 mg/d; n = 3), blonanserin (12–24 mg/d; n = 2), aripiprazole (24 mg/d; n = 1), haloperidol (30 mg/d; n = 1), chlorpromazine (450 mg/d; n = 1), or i.v. haloperidol (5–10 mg/d; n = 3). During the course of ECT, 3 subjects were on a stable dose of antipsychotics, 7 subjects had antipsychotics dosage decreased, and 3 subjects had antipsychotics dosage increased.

Mood stabilizers were withdrawn prior to the first ECT session. The use of benzodiazepines was permitted during the study period. Routine psychotherapy was practiced regularly.

Assessment of Clinical Symptoms

Clinical symptomatic scores were assessed using the 17-item (Hamilton Rating Score for Depression [HAMD]) for patients with MD and the Brief Psychiatric Rating Scale (BPRS) for patients with SCZ. HAMD 17-items were assigned to the following 5 subscales: core symptom (items 1, 2, 7, 8, 10, 13); sleep (items 4, 5, 6); activity (items 7, 8); psychic anxiety (items 9, 10); and somatic anxiety (items 11, 12, 13) in accordance with a previous report (Seretti et al., 1999). Each patient’s symptoms were assessed prior to the first ECT session (baseline, pre-ECT) and a day after the last ECT session (post-ECT) by the same psychiatrist. Responders to ECT were defined as demonstrating a 50% decrease in HRSD score in MD patients or a 30% decrease in BPRS score in SCZ patients.

MMPs and TIMPs Assay

Venous blood samples were taken in the morning (between 7:00 and 8:00 AM) at pre-ECT and post-ECT. Blood samples were drawn into anticoagulant-free tubes. They were kept at room temperature for 1 hour, and serum was separated by centrifugation at 3000 rpm for 15 minutes at 4°C. Serum samples were stored at -80°C until assay. Serum levels of MMP-2, MMP-9, TIMP-1, and TIMP-2 were measured using ELISA (Quantikine ELISA, R&D Systems, Minneapolis, MN) according to the manufacturer’s instructions.

Statistical Analysis

The data are shown as the mean ± SD. The normal distribution of data was tested by the Shapiro-Wilk and the Kolmogorov-Smirnov tests, and statistical analysis was performed by nonparametric tests. A Kruskal-Wallis test was used to evaluate the significant difference in the parameters (clinical and laboratory values) among the 3 groups (MD, SCZ, and control). The Bonferroni test was performed as the posthoc test. Significant differences in the parameters between the 2 groups of patients with MD and SCZ were evaluated using the Mann-Whitney U-test. A chi-square test was used for categorical variables. A Wilcoxon signed-rank test was used to evaluate the statistical differences in the parameters between pre-ECT and post-ECT. Spearman’s correlation evaluated the possible relationship between the clinical symptoms and serum levels. The receiver operating characteristic (ROC) curves for the assessment of specificity and sensitivity of MMPs and TIMPs were calculated to discriminate between the MD group and the control group. The areas under the ROC curve (AUC) were calculated for each MMPs and TIMPs as well. Statistical significance after logistic regression between the 2 AUCs was determined. Statistical analysis was conducted by logistic regression, analyzing diagnosis value of single and combined detection of MMPs. Statistical significance was defined as P < .05. Analyses were performed using SPSS version 22.0 for Windows (IBM Japan Corporation, Tokyo, Japan).

Results

Clinical Data

The clinical data of the 3 groups (MD, SCZ, and control) are presented in Table 1. Gender and age did not significantly differ between the 3 groups. Patients with MD were significantly older and their duration of illness was shorter compared with the SCZ group. Duration of current episode, number of ECTs, and duration of the ECT course did not differ between the MD and SCZ groups. There were no differences between the dose equivalence of imipramine of pre-ECT and post-ECT in the MD group and also no differences between the dose equivalence of chlorpromazine of pre-ECT and post-ECT in the SCZ group.

Serum Levels of MMPs and TIMPs at Pre-ECT in the MD Group Compared with the SCZ Group and Control Group

Serum levels of MMP-2 in the MD group with depressive episodes at pre-ECT were significantly lower than those of the control group (Figure 1A; P = .023), whereas there were no significant differences for the serum levels of TIMP-2, MMP-9, and TIMP-1 between the MD group and the control group (Figure 1B-D). Serum levels of MMP-2, MMP-9, TIMP-1, and TIMP-2 in the MD group at pre-ECT were not significant different compared with those of the SCZ group with psychotic episodes at pre-ECT. Additionally, serum levels of MMPs and TIMPs were not significantly different between MD patients with either MD (unipolar) or bipolar disorder (bipolar) at pre-ECT (MMP-2, unipolar = 165.9 ± 25.0 ng/mL vs bipolar = 159.4 ± 26.8 ng/mL, P = .512; TIMP-2, 63.1 ± 7.6 ng/mL vs 66.6 ± 6.2 ng/mL, P = .259; MMP-9, 553.9 ± 218.8 ng/mL vs 604.6 ± 310.5 ng/mL, P = .668; TIMP-1, 150.5 ± 39.4 ng/mL vs 148.0 ± 23.2 ng/mL, P = .571).

In the ROC curve analysis of diagnosis, the AUC of MMP-2, MMP-9, TIMP-1, and TIMP-2 at pre-ECT between the MD and control groups were 0.738, 0.603, 0.674, and 0.675, respectively. When combining MMP-9 and MMP-2, the combined AUC was 0.745.

Alterations of Serum Levels of MMPs and TIMPs in the MD and SCZ Groups over the Course of ECT

The scores for depressive symptoms evaluated by HAMD in the MD group and the scores of psychotic symptoms evaluated...
Controls either pre-ECT or post-ECT (data not shown).

Correlation between Serum Levels of MMPs and TIMPs and Clinical Symptomatic Scores in the MD and SCZ Groups

Correlation coefficients were calculated between serum levels of MMPs and TIMPs and clinical symptomatic scores evaluated by HAMD for MD and by BPRS for SCZ, combining results from pre-ECT and post-ECT (Table 2). In the SCZ group, there was no significant correlation between serum levels of MMPs, TIMPs, and total BPRS scores (Table 2). However, in the MD group, serum levels of TIMP-1 and TIMP-2 did not correlate with total HAMD score (Table 2). Furthermore, no significant correlations were observed between TIMPs and subscale HAMD scores (Table 3).

By BPRS in the SCZ group significantly decreased following ECT (Table 1). All patients with MD were responders to ECT. Eleven of 13 patients with SCZ (84.6%) were responders to ECT. Both nonresponding SCZ patients were diagnosed with paranoid-type SCZ.

There was a statistically significant increase in serum levels of MMP-2 in the MD group over the course of ECT (P = .046) but no significant change observed in the SCZ group (P = .650) (Figure 1A). There were statistically significant decreases in serum levels of MMP-9 in both the MD and SCZ groups following ECT (MD group, P = .003; SCZ group, P = .019) (Figure 1C). Among the 2 nonresponders to ECT in the SCZ group, one patient had an increase in serum level of MMP-9 and the other had a decrease in serum level of MMP-9 after the course of ECT (data not shown).

Serum levels of TIMP-2 and TIMP-1 did not significantly change over the course of ECT in both the MD and SCZ groups (Figure 1B, D).

Relationship between Serum Levels of MMPs and TIMPs at Pre-ECT and Post-ECT and Subject Characteristics of the MD Group

No significant correlations were observed in the MD group between subject characteristics (gender, age, age of onset, duration of illness, duration of current episode, or dose of medication) and serum levels of MMP-2, MMP-9, TIMP-1, and TIMP-2 at either pre-ECT or post-ECT (data not shown).
Discussion

The current study demonstrated that serum levels of MMP-2 were specifically reduced in MD patients with depressive symptoms applicable to ECT and that serum levels of both MMP-2 and MMP-9 were significantly altered in opposing directions in a depressive state-dependent manner following ECT. In addition, alterations of MMP-2 and MMP-9 appear to be associated with certain depressive symptoms such as not only core symptom, but also somatic anxiety and activity.

The current study is the first to demonstrate a significant negative association between serum levels of MMP-2 and clinical scores of depressive symptoms during the course of ECT in MD patients. A previous proteomic study demonstrated that the plasma levels of MMP-2 in depressive patients were significantly lower than those of control subjects, and plasma levels of MMP-2 in schizophrenic patients were the same as those of control subjects (Domenici et al., 2010). The study, however, measured MMPs at only one time point, utilized a proteomics method, and did not evaluate patient symptoms. Despite these limitations, the previous findings parallel the current findings.

It is currently unknown why circulating levels of MMP-2 declined and are associated with levels of MMP-9 in the MD patients in a depressive state. MMP-2 is constitutively expressed in almost all human tissues, but mainly by endothelial and epithelial cells and fibroblasts (Sbardella et al., 2012). Within the central nervous system, astrocytes are a major source of MMP-2 and presumably drive physiological remodeling of the blood brain barrier (BBB) (del Zoppo et al., 2007; Candelario-Jalil et al., 2011). MMP-2 is detectable in significant serum concentrations under physiological conditions and is linked to homeostatic functioning (Sbardella et al., 2012). The current study showed a reduction of MMP-2 in MD patients before ECT and an increase in MMP-2 after a course of ECT. A number of studies have demonstrated significant reductions of glia, mainly astrocytes, in the postmortem brain of MD patients (Ongur et al., 1998; Cotter et al.,

Another postmortem brain study demonstrated that coverage of blood vessels by astrocyte endfeet in the prefrontal cortex was significantly reduced in patients with MD (Rybakowski et al., 2013). The decline in glia within brain vasculature areas associated with mood function suggests the possibility of reductions in microenvironmental cellular components of the BBB, which is composed of astrocytes and vascular endothelial cells, in MD patients. A clinical finding pointed out that serum levels of MMP-2 were decreased in patients suffering from subarachnoid hemorrhage, in which the BBB is in fact compromised (Horstmann et al., 2006). Decreased MMP-2 in the circulation in MD patients, then, suggests a small compromise of the BBB compared with a gross compromise observed with subarachnoid hemorrhage. The increase of serum levels of MMP-2 in MD patients after the ECT course could be associated with the remodeling of gliovascular units, which is supported by previous ECT findings showing gliogenesis and angiogenesis (Hellsten et al., 2005; Wennstrom et al., 2006; Bouckaert et al., 2014). Further, this MMP-2-related phenomenon could lead to increased incidences of inflammatory states such as production of MMP-9 through a disruption in the BBB in the brain of MD patients, because expression of MMP-9 is regulated not only by immune cells in response to inflammatory events (Van den Steen et al., 2002; Sbardella et al., 2012) but also directly by MMP-2 activity (Dzwonek et al., 2004; Romi et al., 2012). Thus, future studies will be needed to clearly establish evidence of a MMP-2-related “dysregulated BBB” and concurrent alteration of MMP-9 in MD patients by examining samples from patients such as postmortem brain and cerebrospinal fluid.

In the current study, the serum levels of MMP-9 in MD patients was not significantly different from that of the control group before ECT, but MMP-9 significantly decreased following ECT. In addition, a significant positive correlation was observed between MMP-9 and HAMD scores. Similar to the current

**Figure 2.** Correlation between serum levels of matrix metalloproteinases (MMPs) and total Hamilton Rating Scale for Depression (HAMD) score in patients with mood disorders (MD) before and after a course of ECT. (A) Significant negative correlation between serum levels of MMP-2 and total HAMD score. (B) Significant positive correlation between serum levels of MMP-9 and total HAMD score. (C) Significant negative correlation between serum levels of MMP-2 and MMP-9. Pre-ECT values (●) and post-ECT values (○); n = 21, *P < .05.
findings, a previous study found that HAMD scores and serum levels of MMP-9 were positively correlated and there was no difference between depressed patients and controls in serum levels of MMP-9 (Yoshida et al., 2012). Others, however, have found that plasma levels of MMP-9 in depressed patients were significantly higher than those of the controls, which remained elevated even following drug treatment (Rybakowski et al., 2013). Possible reasons for the discrepancy between the current findings and the findings of increased MMP-9 in depressed patients include differences in subject age, severity of symptoms, choice of symptom rating scale, and treatment protocol. It is also possible that circulating MMP-9 is considerably sensitive to psychosocial stress even in healthy individuals (Garvin et al., 2009).

The mechanism by which ECT reduces serum levels of MMP-9 is unknown. An inflammatory state has been proposed as the substrate of MD, since circulating proinflammatory cytokines increase with the severity of mood disturbance symptoms (Felger and Lotrich, 2013; Rosenblat et al., 2014) and cytokine levels decrease after the ECT course (Hestad et al., 2003; Rotter et al., 2013). It is possible that in a depressive episode, the homeostatic state maintained by the immune system could be altered by changes in expression of proinflammatory cytokines and MMPs, and these alterations could be normalized through ECT treatment. The decreased MMP-9 levels in both MD and SCZ groups following ECT could reflect a common involvement of MMP-9 in psychiatric disorders. Fragile X syndrome, psychiatric disorders associated with anxiety, compulsive-repetitive behaviors, and social communication deficits have been associated with changes in MMP-9 levels. Knockout of the MMP-9 gene improved symptoms in a mouse model of Fragile X syndrome and reduced dendritic spine abnormalities (Sidhu et al., 2014). A clinical trial of the antibiotic minocycline decreased MMP-9 levels and appeared to attenuate the symptoms of Fragile X syndrome (Dziembowaska et al., 2013). These findings, combined with the current findings, suggest that decreasing MMP-9 alleviates some types of psychiatric disorders.

As biomarkers for MD, ROC analysis in the current study demonstrated that the AUC for both MMPs and TIMPs prior to ECT was found to be 0.745 at its peak, which does not suggest that either ligand would have high diagnostic value as a biomarker. Because serum levels of MMP-2 was negatively correlated to certain depressive symptoms, to which MMP-9 was positively correlated, both MMP-2 and MMP-9 could serve as biomarkers for specific depressive states or symptoms with greater accuracy if possibly combined with other inflammatory ligands such as cytokines.

To place the current findings into perspective, there are a few limitations that should be mentioned. While the total sample size of the current study was small, significant correlations were nonetheless observed. Expanding the cohorts could reveal significant changes and correlations in MMP and TIMP. Second, it is unclear if blood concentrations of MMP and TIMP reflect those in the brain. There are some reports that found no correlation between blood and CSF concentrations of MMPs (Horstmann et al., 2010; Niebroj-Dobosz et al., 2010). Therefore, it is possible that the dynamics of MMPs, as well as TIMP, in the brain are different from those in peripheral tissues. To overcome this issue, direct assessment of MMPs in CSF from MD patients could be highly useful. Finally, the effect of medications on serum MMPs levels is not well understood. Although there were no statistically significantly differences before and after ECT on the equivalence of both imipramine and chlorpromazine, patients were allowed to use medication during the course of ECT. A future investigation could include drug-naïve patients to evaluate the effects of medications on MMP, at least before treatments.

**Conclusion**

Serum levels of MMP-2 were significantly decreased in MD patients with depressive episodes, and a course of ECT in these patients significantly increased MMP-2 but decreased MMP-9. Also in MD patients, there were significant correlations between depressive symptoms and serum levels of MMP-2 and MMP-9, in opposite directions, in response to ECT. The findings suggest that alteration of homeostasis linked to inflammation lead to changes in levels of MMP-2 and MMP-9, which occurs in a disease-specific manner and depend on the severity of depressive symptoms, which are in turn sensitive to ECT treatment.
