33

34 **Abstract**

35 **BACKGROUND:** Foot arch dynamics play an important role in

36 dynamic postural control. Association between foot arch dynamics and

37 postural control among adolescent athletes remains poorly explored.

38 **OBJECTIVE:** To examine the relationship between foot arch

39 dynamics, intrinsic foot muscle (IFM) morphology, and toe flexor

40 strength and dynamic postural stability after jump landing and

41 repetitive rebound jump performance in competitive adolescent

42 athletes.

43 **METHODS:** Based on foot arch dynamics, evaluated from relative

44 change in the foot arch height in sitting and standing positions, 50

45 adolescent athletes were classified as stiff, normal, or flexible. IFM

46 morphology was evaluated by ultrasonography. Dynamic postural

47 stability index (DPSI) was measured as participants jumped and  
48 landed with the right leg onto a force plate, whereas repetitive rebound  
49 jumping performance was assessed using the jump height and reactive  
50 jump index.

51 **RESULTS:** The stiff group had a significantly worse DPSI and  
52 vertical stability index than the normal group ( $p=0.26$ ,  $p=0.44$ ,  
53 respectively), and worse anteroposterior stability index (APSI) values  
54 than the flexible group ( $p=0.005$ ). Multivariate regression models of  
55 the relationship between the APSI and foot arch dynamics showed  
56 adequate power (probability of error = 0.912).

57 **CONCLUSIONS:** Increased foot arch stiffness negatively affects  
58 dynamic balance during jump-landing, which may deteriorate their  
59 performance.

60 **Keywords:** jump; postural balance; ultrasonography

61

## 62 **1. Background**

63 The foot arch has a spring-like quality that absorbs shock during  
64 movement, reduces ground reaction forces [1], and stores and releases  
65 elastic strain energy [2]. The intrinsic foot muscles (IFMs) and tendons

66 that form the foot arch help in shock absorption by the foot during  
67 motion, and play a role in foot flexibility. Furthermore, the IFMs  
68 contribute to the foot stiffness needed to transmit adequate forces [3],  
69 as well as to postural control [4]. However, the relationship between  
70 postural control and the foot arch height (FAH) has not been examined,  
71 and factors contributing to postural control need to be investigated in  
72 more detail. In addition, most of these reports are based on adults, and  
73 little has been examined in adolescents, who are said to have relatively  
74 flexible feet. Notably, reduced postural control caused by  
75 physiological abnormalities of the foot arch, including the pes planus  
76 (flat foot) and pes cavus (high foot), may lead to musculoskeletal  
77 injuries such as ankle sprains [5].

78           Reduced arch flattening is associated with toe-flexor muscle  
79 strength. A study of 448 feet of healthy young adults showed that FAD  
80 was associated with relative toe flexor strength from the sitting to  
81 standing position [6]. In addition, a comparison of foot morphology  
82 and toe flexor strength between judo athletes and 24 physically active  
83 healthy subjects each showed that the judo group had lower arch height  
84 and stronger toe flexor strength [7]. These findings suggest that FAD

85 and toe grasping muscle strength are involved in athletic  
86 characteristics. Additionally, force attenuation and postural control  
87 during landing are essential factors for preventing sports injuries [8].  
88 To our knowledge, the association between foot arch dynamics, cross-  
89 sectional area (CSA) of selected muscles, and physical performance,  
90 including postural control during jump-landing by adolescent  
91 competitive athletes, has not yet been explored. Hence, this study was  
92 performed to investigate whether foot arch dynamics, IFM  
93 morphology, and toe flexor strength are related to dynamic postural  
94 stability and repetitive rebound jump performance after jump-landing  
95 performed by adolescent competitive athletes. We hypothesized that  
96 foot arch dynamics would be associated with the maintenance of  
97 dynamic postural stability among adolescent competitive athletes.

98

## 99 **2. Materials and methods**

### 100 *2.1 Experimental procedure*

101 Fifty adolescent competitive athletes (28 boys:  $13.5 \pm 1.1$   
102 years old, and 22 girls;  $13.0 \pm 0.98$  years old) who underwent medical  
103 and physical examinations at the Sports Medical Center at Hiroshima

104 University Hospital participated in this cross-sectional study,  
105 conducted between July 2021 and August 2021 (Table 1). Only those  
106 who had been selected by Hiroshima City as specially strengthened  
107 athletes in 2021 were enrolled in the study. The included athletes  
108 played sports such as rugby, badminton, sailing, judo, handball,  
109 wrestling, archery, water polo, figure skating, table tennis, kendo,  
110 hockey, and basketball. The exclusion criteria were as follows: any  
111 injury that required taking a break from sports activities within the past  
112 3 months, any error during any of the measurements, any neurological  
113 disorder that might have affected balance, and any lower extremity  
114 injury. This study protocols complied with the tenets of the Declaration  
115 of Helsinki and was approved by the Ethical Committee for  
116 Epidemiology at Hiroshima University (file number: E-941).  
117 Informed consent was obtained from the participants, guardians and  
118 instructors of all study participants.

119           The foot posture index, which is an assessment of the internal  
120 and external rotations of the foot in the standing position, was used to  
121 determine the pes planus alignment [9]. The index consists of the  
122 following six items: palpation of the talar head, observation of the

123 supra- and inferior curvature of the external malleolus, calcaneal  
 124 frontal plane position, prominence in region of talonavicular joint,  
 125 congruence of medial longitudinal arch, and abduction/adduction of  
 126 forefoot on rearfoot. Each item is scored on a 5-point scale (-2, -1, 0,  
 127 +1, +2). The lowest score of -12 indicates external rotation of the foot,  
 128 and the highest score of +12 indicates internal rotation. Previous study  
 129 indicate that the use of only the five image-based criteria of the FPI-6  
 130 demonstrates strong intra-rater reliability [10].

131           The FAH was measured using a ruler as the perpendicular  
 132 distance from the navicular tuberosity to the floor in the sitting and  
 133 standing positions [2]. Semi-permanent ink was used to mark the skin  
 134 over the navicular tuberosity, the location of which was determined by  
 135 palpation. The FAH was measured with no weight-bearing on each  
 136 foot in the sitting position and with approximately 50% weight-bearing  
 137 on each foot in the standing position (Fig 1). These assessments were  
 138 performed by one physical therapist with at least 5 years of experience.  
 139 The FAH relative to the height was determined as follows:

140

$$141 \quad \text{relative FAH} = \left( \frac{\text{FAH}}{\text{height}} \right) \times 100$$

142

143           A digital grip dynamometer (T.K.K.3361; Takei Scientific  
144 Instruments, Niigata, Japan) comprising strain-gauge force  
145 transducers was used. Participants were asked to gradually increase  
146 their toe flexor strength for 0 to 3 s, with a maximum force maintained  
147 for 2 s. The force exerted by the metatarsophalangeal joints when the  
148 bar was pulled was measured. The foot was placed on a digital grip-  
149 measuring dynamometer, and fixed to a heel stopper and belt. During  
150 measurements, participants were instructed to perform the task in the  
151 sitting position with their hip and knee joints flexed at 90° and their  
152 arms in front of their chests [6,11]. Three measurements were recorded,  
153 and the average was calculated in Newton meters divided by body  
154 weight (Nm/kg).

155           The CSA of the plumpest parts of selected IFMs were  
156 measured using B-mode ultrasonography (HI Vision Avius; Hitachi  
157 Aloka Medical, Tokyo, Japan) with an 8-MHz linear array probe.  
158 These measurements were performed based on previous studies  
159 [12,13]. Morphometric evaluations of the IFMs using ultrasound  
160 have been shown to be reliable in previous studies [14,15]. The IFMs

161 selected for this study were the abductor hallucis, flexor hallucis brevis,  
162 and flexor digitorum brevis, as they are the main supporting muscles  
163 of the medial longitudinal arch that support the foot structure [16,17].  
164 The point on the skin at which the probe was to be placed was marked  
165 with semi-permanent ink. When performing the measurements, the  
166 probe was placed on the skin with minimal pressure. Subsequently,  
167 participants were instructed to maintain a prone position with their  
168 knees flexed at 90° and their ankles maintained in a neutral position.  
169 The probe was placed anterior to the medial malleolus in a line  
170 perpendicular to the long axis of the foot, and the CSA image of the  
171 abductor hallucis muscle was recorded. Next, the probe was placed  
172 perpendicular to a line parallel to the flexor hallucis brevis muscle, to  
173 record its CSA image. Finally, for recording the CSA image of the  
174 flexor digitorum brevis muscle, the probe was placed perpendicular to  
175 a line connecting the third toe and medial calcaneal tuberosity. This  
176 assessment was made by one physical therapist with at least 5 years of  
177 experience of using ultrasound.

178           A one-leg jump with forward landing was performed to  
179 assess the dynamic postural stability index (DPSI) score of the

180 participants. The starting position of the participants was at a distance  
181 of 40% of their height away from the force platform (AccuGait; AMTI,  
182 Hiratsuka, Kanagawa, Japan, 49.5 cm × 49.5 cm). A 30-cm high hurdle  
183 was set at the midpoint of the line connecting the starting position and  
184 edge of the force plate. Participants were asked to jump (forward) over  
185 hurdles with both feet, and land on the force plate with their right foot,  
186 and were instructed to stabilize as soon as possible after landing, place  
187 their hands on their pelvis, and remain still for 10 s. Movement of the  
188 upper limbs during the jump was not restricted; however, it was limited  
189 to placing the hands on the pelvis after stabilization. The landing task  
190 was practiced three times, and a 1-min rest was provided after each  
191 test. The trial was discarded if the jump was unsuccessful, for instance,  
192 if the participant touched the hurdle, fell when landing, landed on the  
193 ground outside the force plate, or had their right limb touch the left.  
194 This method was previously reported to have high inter-session  
195 reliability, with an intra-class correlation coefficient (3,k) of 0.86 [18].  
196 (3,k) represents the inter-rater reliability of using the mean of multiple  
197 measurements with relative agreement.

198 The participants' repetitive rebound jump performance was

199 evaluated using the Optojump™ system (Microgate, Bolzano, Italy).  
200 This system uses two parallel infrared photocell bars; one bar was  
201 placed 0.3 cm above the surface as a transmitter unit with 96 light-  
202 emitting diodes, whereas the other was placed as a receiver. To prevent  
203 the jump performance from being affected, participants were asked to  
204 place their hands on their pelvis and repeat jumping and landing with  
205 their dominant foot five times. The dominant foot was defined as the  
206 ball kicking foot. Participants were further instructed to stand with  
207 their knees initially extended and then flexed as they jumped up and  
208 landed in the same spot at all times, while looking ahead. Participants  
209 were required to jump as high as possible with the shortest possible  
210 contact time between the floor and their feet, so that they could  
211 immediately start the next jumping motion. When the participant's  
212 foot contacted the floor, the light between the two infrared bars was  
213 interrupted, and the monitoring system sensor recorded at a sampling  
214 frequency of 1000 Hz. Two sets of five rebound jumps were used, and  
215 a 5-min rest was provided between sets. Of the five rebound jumps,  
216 the third through fifth jumps were used for analysis to obtain a stable  
217 value; this method exhibited good inter-day reliability [19].

218

219 *2.2. Data collection*

220 Foot arch dynamics refers to the relative change in the FAH  
221 in the sitting position without weight applied to the feet, and in the  
222 standing position with approximately 50% of the body weight applied  
223 to each foot [7]. The equation for calculating foot arch dynamics is as  
224 follows:

225

$$226 \quad \text{Foot arch dynamics (\%)} = \frac{(\text{FAH sitting} - \text{FAH standing})}{\text{FAH sitting}} \times 100$$

227

228 If the foot arch dynamics is within  $\pm 1$  standard deviation (SD) of the  
229 mean, the foot is classified as normal. If the foot arch dynamics is  $< 1$   
230 SD from the mean, the foot is classified as stiff, and if the LAA is  $> 1$   
231 SD from the mean, the foot is classified as flexible. [20].

232 The DPSI values were calculated using the ground reaction force  
233 (GRF) within 3 s of the first contact, and the vertical GRF more than  
234 5% of the body weight. The force plate values were normalized to the  
235 participant's body weight, following which the GRF data were  
236 filtered using a zero-lag, second-order, low-pass Butterworth filter

237 with a cutoff frequency of 20 Hz. The DPSI values were calculated  
 238 from the filtered data using MATLAB 2021a (MathWorks, Natick,  
 239 MA, USA). The DPSI values are a composite of the anteroposterior,  
 240 mediolateral, and vertical directions of GRFs in all planes, and are  
 241 sensitive to force changes in the anterior (anteroposterior stability  
 242 index [APSI]), mediolateral (mediolateral stability index [MLSI]),  
 243 and vertical (vertical stability index [VSI]) directions. These indices  
 244 were converted to APSI, MLSI, and VSI values using the following

245 formulae [16]:1) 
$$\text{DPSI} = \frac{\sqrt{\sum(0-\text{GRFx})^2 + \sum(0-\text{GRFy})^2 + \sum(0-\text{GRFz})^2}}{\text{Number of data points}} \div$$

246 Body weight

247 2) 
$$\text{APSI} = \frac{\sqrt{\sum(0-\text{GRFx})^2}}{\text{Number of data points}} \div \text{Body weight}$$

248 3) 
$$\text{MLSI} = \frac{\sqrt{\sum(0-\text{GRFy})^2}}{\text{Number of data points}} \div \text{Body weight}$$

249 4) 
$$\text{VSI} = \frac{\sqrt{\sum(0-\text{GRFz})^2}}{\text{Number of data points}} \div \text{Body weight}$$

250 Further analysis was performed using the average of three successful  
 251 trials [17]. GRF data used for the DPSI calculations of dynamic  
 252 posture control were collected at a sampling frequency of 200 Hz.  
 253 Higher DPSI values indicated worse dynamic postural stability [21].

254 Rebound jump performance variables (jump height [cm],  
 255 contact time [s], and reactive jump index [m/s]) were automatically

256 calculated using the Optojump™ software (Optojump™ Next  
257 software, version 1.9.9.0). The strength of reactivity was assessed  
258 using the reactive jump index, which is a measure of an athlete's ability  
259 to efficiently absorb force (eccentrically) and generate propulsion  
260 (concentrically) within a specific time [19,22]. Higher reactive jump  
261 index values indicate better rebound jump performance. The average  
262 of the data from the three successful trials was used for additional  
263 analyses. Jump height was calculated as follows:

264

$$265 \quad \text{Jump height} = (1/2 \times \text{Tair} \times g)^2 \times (2g) - 1$$

266

267 where "Tair" is the time of flight (s) between the recorded force on the  
268 force plate and "g" is the acceleration due to gravity (9.81 m/s<sup>2</sup>). The  
269 reactive jump index was calculated as follows:

270

$$271 \quad \text{Reactive jump index} = \frac{1}{8} \times g \times \frac{\text{Tair}^2}{\text{contact time}}$$

272

273 These analyses were performed using the mean value of the three  
274 repeated jumps.

275

276 *2.3 Statistical analysis*

277 All measurement values were analyzed using SPSS software  
278 (version 27.0; IBM Japan, Tokyo, Japan). Normality was confirmed  
279 using the Shapiro–Wilk test, and normally distributed variables are  
280 presented as the mean  $\pm$  SD. Participants were stratified into three  
281 groups (flexible, normal, and stiff) according to the mean and SD  
282 values of their foot arch dynamics. Chi-square tests were used to check  
283 for differences in the male-female ratios between the three groups. A  
284 one-factor analysis of variance was used to investigate differences in  
285 the morphological characteristics of the foot, CSA of the IFMs, DPSI  
286 values, and repetitive rebound jump values. The relationship between  
287 the foot arch dynamics and DPSI was examined using multiple linear  
288 regression with the stepwise method. Foot arch dynamics was defined  
289 as the dependent variable, and DPSI was defined as an independent  
290 variable. The significance level was set at 5%. The post hoc power  
291 analysis was performed as previously described [22]. This procedure  
292 estimated the power of the omnibus F-test by considering the  
293 population effect size ( $f^2$ ), probability of error ( $\alpha$ ), sample size, and

294 number of predictors included in the regression model [23].

295

### 296 **3. Results**

297           There were no significant differences in the physical  
298 characteristics of the participants among all the groups (Table 1). Table  
299 2 shows the foot characteristics of participants in the stiff, normal, and  
300 flexible groups. Overall, there were no significant differences in the  
301 CSA of the abductor hallucis, flexor hallucis brevis, and flexor  
302 digitorum brevis muscles among the groups ( $p=0.863$ ,  $p=0.913$ , and  
303  $p=0.983$ , respectively). Table 3 shows the DPSI values and rebound  
304 jump performance of the stiff, normal, and flexible groups. The stiff  
305 group had significantly higher DPSI and VSI values than the normal  
306 group ( $p=0.026$ ,  $p=0.044$ , respectively), as well as a significantly  
307 higher APSI value than the flexible group ( $p=0.005$ ). There were no  
308 differences in DPSI or VSI values between the stiff and flexible groups,  
309 or between the normal and flexible groups. Additionally, there were no  
310 significant differences in the jump heights and reactive jump indices  
311 among the groups. Finally, only APSI was correlated with foot arch  
312 dynamics. In the post hoc power analysis, the multivariate regression

313 models for the association between the APSI and foot arch dynamics  
314 showed adequate power ( $\beta=-0.45$ ;  $p=0.001$ ; 95% confidence interval,  
315  $-50.175$  to  $-13.502$ ;  $R^2=0.127$ ; probability of error = 0.912) (Table 4).

316

#### 317 **4. Discussion**

318 This is the first experimental study to explain the integration  
319 of the force perception of the foot and mechanical function of the foot  
320 arch after jump-landing performed by adolescent competitive athletes.  
321 The main finding of this study was that adolescent competitive athletes  
322 with stiff foot arches had considerably low postural control after jump-  
323 landing. In addition, the APSI, which is a measure of dynamic postural  
324 balance, was associated with foot arch dynamics. Our findings indicate  
325 that the mechanism of postural control after jump-landing was  
326 controlled by foot arch dynamics associated with stretching and  
327 contraction of the foot muscle–tendon complex.

328

329 Overall, the relationship between foot arch stiffness and  
330 balancing ability remains controversial. The height of the medial  
331 longitudinal arch positively correlates with rebound jump ability [2].

332 Additionally, the stiffness of the intrinsic plantar muscles that make up  
333 the foot arch increase the sensitivity of the muscle spindles, which  
334 improves a balance ability, through improved kinesthesia in athletes  
335 [26→24]. Notably, a previous study by Simkin et al. [27→25] reported  
336 that a low-arch foot was better at absorbing shock than a high-arch foot.  
337 In the present study, the association between the dynamic function of  
338 the foot arch and postural control after jump-landing in adolescent  
339 competitive athletes was clarified. Increased foot arch stiffness leads  
340 to the deterioration of the dynamic postural control in the anterior and  
341 posterior directions in adolescent athletes. Previous studies of arch  
342 structure and injury patterns have demonstrated that ankle and foot  
343 injuries occur more frequently in those with a high arch than in those  
344 with a low arch [5]. Therefore, adequate foot flexibility may play an  
345 important role in postural control and injury prevention.

346           The foot arch acts as a spring that stores and releases elastic  
347 energy as the load on the foot increases. This function is accomplished  
348 by achieving changes in the foot arch, which comprises extrinsic and  
349 intrinsic foot muscles. In particular, the IFMs and tendons maintain the  
350 foot arch and help it to adapt during standing and while changing

351 walking speed [23 → 26]. Therefore, the entire foot may become  
352 unstable if the intrinsic foot muscles and tendons are not functioning  
353 properly during movement. This may reduce the ability of the foot to  
354 adapt to dynamic movement, leading to static and dynamic imbalances  
355 [24→27]. Furthermore, the relationship between foot arch dynamics  
356 and the performance of jump-landing may be associated with the  
357 sensorimotor interaction among the components of the foot,  
358 contributing to the consolidation of the sensory information necessary  
359 for dynamic postural control [17,25→27].

360           This study has some limitations. First, our sample size was  
361 too small to allow for a comparison of athletes who performed  
362 different types of sports. Future research involving large-scale,  
363 targeted recruitment of participants involved in different types of  
364 sports is necessary. Second, sex differences in participants were not  
365 examined. A previous study reported that women had lower arches  
366 than men and that there was a gender difference [28]. Therefore, we  
367 intend to increase the number of subjects and examine the relationship  
368 between foot arch dynamics and dynamic postural control from the  
369 perspective of gender differences. Finally, the present study has a

370 strength to investigate the association between the foot arch dynamics  
371 and dynamic postural stability in adolescent competitive athletes,  
372 however it is only a cross-sectional study. Future studies should  
373 prospectively examine how the actual incidence of sports injuries  
374 relates to the foot arch dynamics and dynamic postural control of the  
375 present study and should also be linked to the prevention of injury  
376 occurrence during adolescence.

377

## 378 **5. Conclusions**

379 In conclusion, the foot arch dynamics play an important role  
380 in the dynamic postural control of adolescent competitive athletes.  
381 From the viewpoint of daily clinical practice, identifying and screening  
382 adolescent athletes with foot arch stiffness is important to improve  
383 physical performance and prevent sports injuries..
